Gallium Arsenide

23. Gallium Arsenide

The history of gallium arsenide is complicated because the technology required to produce GaAs devices has been fraught with problems associated with the material itself and with difficulties in its fabrication. Thus, for many years, GaAs was labelled as “the semiconductor of the future, and it will always be that way.” Recently, however, advances in compact-disc (CD) technology, fibre-optic communications and mobile telephony have boosted investment in GaAs research and development. Consequently, there have been advances in materials and fabrication technology and, as a result, GaAs devices now enjoy stable niche markets.

The specialised uses for GaAs in high-frequency and optoelectronic applications result from the physical processes of electron motion that allow high-speed and efficient light emission to take place. In this review, these advanced devices are shown to result from the physical properties of GaAs as a semiconducting material, the controlled growth of GaAs and its alloys and the subsequent fabrication into devices.

Extensive use is made of chapters from “Properties of Gallium Arsenide, 3rd edition” which I edited with the help of *Prof. G. E. Stillman* [23.1]. This book was written to reflect virtually all aspects of GaAs and its devices within a readable text. I believe that we succeeded in that aim and I make no apologies in referring to it. Readers who need specialised data, but not necessarily within an explanatory text, should refer to the Landolt-Börnstein, group III (condensed matter) data collection [23.2, 3]. The sub-volumes A1 α (lattice properties) and A2 α (impurities and defects) within volume 41 are rich sources of data for all III–V compounds. Although there are no better sources than the original research papers, I have referred to textbooks where possible. This is because the presentation and discussion of scientific data is often clearer than in the original text, and these books are more accessible to students.

Gallium arsenide (GaAs) is one of the most useful of the III–V semiconductors. In this chapter, the properties of GaAs are described and the ways in which these are exploited in devices are explained. The limitations of this material are presented in terms of both its physical and its electronic properties.

GaAs is one of the compound semiconductors that occur in the zincblende structure. As can be seen in Fig. 23.1, each Ga atom is tetrahedrally bonded to four As atoms in a structure that is similar to the diamond lattice but with alternating Ga and As atoms.

The presence of two types of atoms introduces a small component of ionic bonding into the structure and increases the bond strength above that of the group IV element (Ge) which Ga and As neighbour. As a result the band-gap energy E_g , is increased to 1.518 eV at $T = 0$ K ($E_g = 1.41$ eV at room temperature).

The lattice constant of GaAs at 300 K is 0.565 36 nm, giving a resultant density of 5.3165 g/cm³. At atmospheric pressure GaAs melts near 1238 °C but with the loss of As vapour.

Fig. 23.1 The zincblende lattice of GaAs. The lattice constant a is indicated. (After [23.4])

Although all $\langle 001 \rangle$ atomic planes are equivalent this is not true for $\langle 011 \rangle$ and $\langle 111 \rangle$ planes. In particular, there are two types of $\langle 111 \rangle$ atomic planes; one terminated with Ga atoms only (the $\langle 111 \rangle_A$ planes), the other being terminated with As atoms only (the $\langle 111 \rangle_B$ planes). This makes the $\langle 111 \rangle$ directions strongly polar. A further consequence of the reduced symmetry of the lattice compared with the group IV semiconductors is that GaAs exhibits strong piezoelectric effects.

The easily cleaved directions are the $\langle 110 \rangle$ and $\langle 111 \rangle$ types. The $\langle 110 \rangle$ are the more useful as they allow square sections to be cleaved from a $\langle 001 \rangle$ section wafer, one of the major reasons for the use of $\langle 001 \rangle$ wafers in GaAs device fabrication.

The original interest in GaAs arose from its unusual band structure, compared to that of Si in Fig. 23.2, which demonstrates several attributes that are expected to be interesting for high-speed electronics and optoelectronics.

1. The fundamental band-gap energy of 1.41 eV (300 K) corresponds to a point in the diagram, the Γ point of the Brillouin zone, where both the crystal momentum for holes and electrons is zero. It follows that low-energy electrons and holes can recombine without the moderating influence of phonons that would otherwise be required to conserve momentum. Such direct recombination is expected to result in efficient emission of photons and GaAs would then be the base material for efficient light-emitting diodes (LEDs) and lasers.
2. The effective mass of conduction-band electrons is inversely proportional to the curvature at the bottom of the band and this curvature is considerably greater, and the effective mass is considerably smaller, in GaAs (about $0.063 m_e$) than in silicon (about $1.1 m_e$).

Table 23.1 Selected important properties of pure GaAs at 300 K

Lattice constant (Å)	5.653
Density (g/cm ³)	5.318
Band-gap energy (eV)	1.424
Band-gap type	Direct
Electron mobility (cm ² /Vs)	8500
Hole mobility (cm ² /Vs)	400
Zero-frequency dielectric constant	13.18
Conduction-band effective density of states (cm ⁻³)	4.45×10^{17}
Valence-band effective density of states (cm ⁻³)	7.72×10^{18}
Intrinsic carrier concentration (cm ⁻³)	1.84×10^6

Because the mobility of carriers is inversely proportional to their effective mass, it follows that free electrons in GaAs should be very mobile under the influence of an electric field, resulting in fast devices.

- An additional feature of Fig. 23.2 is the occurrence of subsidiary conduction-band minima near the six points of maximum momentum along the $\langle 100 \rangle$ directions. These are at the so-called L points of the Brillouin zone. These minima are degenerate and at an energy of 0.3 eV above the minimum energy of the conduction band at the Γ point. The relatively small curvature of these X minima results in a large effective electron mass of about $1.2 m_e$. Electrons at these points have a correspondingly low mobility. It follows that the excitation of low-effective-mass free electrons from the Γ point to the L minima, where they have high effective mass, can result in a *reduction* of electron velocity and hence electron current. This is the *transferred electron effect*. The current/voltage characteristics of such a device exhibit a negative differential resistance region, the Gunn effect, and this can be used to generate microwave radiation.
- One property of GaAs, not resulting from Fig. 23.2, is that the material can be produced in a high electrical resistivity, semi-insulating (SI) state. This allows devices to be fabricated on a near-insulating substrate. This is advantageous for high-frequency devices as the parasitic capacitances that occur between Si devices and their substrate, reducing their

Fig. 23.2a,b The band structures of (a) Si and (b) GaAs. The primary band gap of Si is indirect with an energy E_g , of 1.12 eV. However, that of GaAs is direct (both free electrons and holes of low energy have states that correspond to zero crystal momentum at the Γ point of the Brillouin zone). Secondary conduction-band minima occur at 0.31 eV above the primary minimum near points of maximum crystal momenta along the $[111]$ -directions. These are at the L points. (After [23.4])

maximum operating frequency, will be absent in GaAs devices fabricated on SI substrates.

- A further property of great interest is that the lattice constants of GaAs and aluminium arsenide, AlAs, and their alloys, written as $\text{Ga}_{1-x}\text{Al}_x\text{As}$, where x is the atomic fraction of Al, are very similar. This allows different alloys to be grown consecutively without incurring defects due to lattice mismatch. Such heterostructures are not possible with Si and its known alloys.

The predictions made above will be addressed in later sections but first we consider the growth of GaAs single crystals suitable for device use. Subsequently, we consider the epitaxial growth of thin, GaAs-based layers, which are the basis of modern devices, means of processing and the fabrication and properties of important devices.

23.1 Bulk Growth of GaAs

In the simplest terms, GaAs crystals are synthesised by reacting together high-purity Ga and As. Dopants may be added to produce materials of different conduction type and carrier concentration. However, the growth of compounds from the melt is a thermodynamic process and is characterised by the shape of the phase diagram near the solidus at temperatures just below the melting point of the compound. Hurle has published a thorough reassessment of the thermodynamic parameters for GaAs, with and without doping [23.6]. The complete phase diagram for Ga–As, showing the GaAs compound, is shown in Fig. 23.3. However, details near the GaAs solidus are not revealed at this large scale.

The shape of the GaAs solidus is more complicated than indicated in Fig. 23.3. In particular, the congruent point, the maximum melting temperature, corresponds to a GaAs compound containing more As than exists in stoichiometric material (Fig. 23.4).

Fig. 23.3 The complete phase diagram of the Ga–As system at an assumed pressure of As vapour of about 1 atm. The vertical line near 50% composition is crystalline GaAs. (After [23.5])

It follows that growth from a stoichiometric melt results in the growth of a solid phase containing an excess of As of approximately $1 \times 10^{19} \text{ cm}^{-3}$. The solidus is retrograde so that, if thermodynamic equilibrium is maintained, this excess As must be lost from the host as the solid cools. If this As supersaturation cannot be relieved by out-diffusion from the crystal, then it will result in the generation of As-rich second phases (precipitates). Growth from a Ga-rich melt will result in the growth of a stoichiometric crystal. However, the melt will become more Ga-rich as growth proceeds, leading to the growth of solid GaAs that steadily becomes richer in Ga.

Experimental work has shown that the electrical properties of Ga-rich GaAs are poor (undoped Ga-rich GaAs is strongly p-type [23.7]) and this growth regime is rarely used. Although As richness is found in melt-grown GaAs, measured concentrations of excess As do not exceed 10^{17} cm^{-3} [23.8,9]. It is not known how most of the grown-in excess As atoms are lost.

23.1.1 Doping Considerations

Unlike group IV semiconductors where shallow donors are group V atoms only, donors in III–V compounds can occur on either sublattice, as IV_{III} or VI_{V} , where the

Fig. 23.4 The GaAs solidus. The arrow marks the congruent point (After [23.6])

capital letters represent the group in the periodic table from which the donor is selected and the subscript is the sublattice occupied. However, only certain group IV atoms have a suitable solubility on the Ga sublattice for them to be useful and the same situation is true for group VI atoms on As sites.

Similarly, acceptors can be of II_{III} or IV_{V} types. (In principle, group IV atoms can be both acceptors and donors, IV_{III} and IV_{V} respectively, a situation known as *amphotericity*. Silicon, and to a similar extent germanium atoms in GaAs, behave like this.) Once again not all of these occur in practice. The choice of dopant depends mainly on its segregation coefficient and solubility (see [23.6] for a discussion of this point). Figure 23.5 shows most of the known shallow donors and acceptors in GaAs with their ionisation energies. Also shown in this figure are two important impurities that generate levels deeper in the band gap. Cu is an unwanted deep acceptor contaminant but Cr has some technological importance and this element is discussed later.

In melt-grown GaAs, donors are usually either Si_{Ga} or Te_{As} , as each has a satisfactory segregation coefficient and solubility, although other group VI species have been used. Donors experience some degree of auto-compensation with the result that, up to a carrier concentration n of about $3 \times 10^{18} \text{ cm}^{-3}$, the carrier concentration is only about 80% of the added dopant concentration. Thermodynamic analysis has demonstrated that for group VI donors this is a result of the formation of (donor– V_{Ga}) pair defects. Auto-compensation for the case of Si doping is a result of the amphotericity of Si with a fraction, about 10%, of the Si atoms taking up As lattice sites and behaving as shallow acceptors. Above $n = 3 \times 10^{18} \text{ cm}^{-3}$, the carrier concentration tends to saturate and extra donor atoms are involved in vacancy complexes with a drop in electron mobility, the appearance of dislocation loops and a rapid rise in the lattice constant [23.6].

The p-type doping of melt-grown GaAs appears to be much easier. There is no auto-compensation and the solubility of Zn, the most common acceptor dopant in melt-grown GaAs, is over 10^{20} cm^{-3} . The segregation coefficient of Zn in GaAs is close to unity.

Although the partial pressure of Ga above a Ga–As melt at all reasonable temperatures is extremely small and can be ignored, the partial pressure of As vapour (As_2 and As_4) depends sensitively on the melt composition and this can be used to control the ratio of Ga/As in the melt as the crystal grows. Over a stoichiometric GaAs melt at the melting temperature of 1238°C this pressure is approximately two atmospheres (1 atm above

Fig. 23.5 The ionisation energies in eV of the shallow donors and acceptors in GaAs. Also shown are the important deep levels due to Cu and Cr. Cu is an impurity that can be introduced at growth or by processing and causes damaging deleterious effects in devices. Cr was originally used as a deep acceptor to produce semi-insulating GaAs. Its use has fallen since the introduction of LEC and similar growth techniques, see later. (Updated after [23.4])

ambient). It is necessary to control this pressure to retain melt composition and to impede the loss of As from the melt. This has resulted in the development of several growth techniques.

23.1.2 Horizontal Bridgman and Horizontal Gradient Freeze Techniques

The first growth method to be used commercially was the horizontal Bridgman (HB) technique [23.10]. In essence, the growth chamber consists of a horizontal quartz tube, at one end of which is a boat containing the Ga–As melt near the melting temperature (T_m) of 1238°C while the other end is cooler, near 617°C , and contains a small quantity of elemental As, Fig. 23.6.

This As produces the overpressure of As_4 that controls the stoichiometry of the Ga–As melt. The Ga–As melt is often formed by reacting metallic Ga in the growth section with As vapour produced from the As reservoir at the other end. In other processes polycrystalline GaAs is used as the source for the molten Ga–As. The growth can proceed in two ways. In the classical HB technique the initial melt exists in a region at a temperature just above T_m but adjacent to a small temperature gradient. A seed crystal, already placed in the crucible with part of it in the melt while the rest is at a temperature below T_m , will initiate growth. The melt is moved mechanically through the temperature gradient so that the entire melt is gradually cooled below T_m . Eventually, all of the GaAs melt solidifies on the seed as a single crystal and with the same orientation as the seed.

Fig. 23.6 The horizontal Bridgman technique for growing GaAs. The growth takes place in the high-temperature region of the furnace whilst the As vapour pressure is controlled by the presence of elemental As in the low-temperature region. The interface between the melt and the solid is gradually moved until all the GaAs is solidified. (After [23.4])

In a modification to **HB**, the mechanical withdrawal of the GaAs melt through the gradient is replaced by slowly reducing the temperature of the growth region electronically. This is the horizontal gradient freeze (**GF**) method [23.11]. It has the advantage of needing less room and is less sensitive to mechanical disturbance.

In both cases, crystals are best grown along $\langle 111 \rangle$ to reduce the occurrence of twinning. $\langle 001 \rangle$ wafers can be extracted from the $\langle 111 \rangle$ boule by accurate sawing. Advantages of the **HB** and horizontal **GF** methods include the good visibility of the growth procedure, allowing the operator to make modifications as growth takes place. However, grown crystals have a D-shaped cross section because of the shape of the melt in the boat and subsequent wafering. Considerable loss of material is incurred if the wafers are edge-ground to make them circular.

HB and horizontal **GF** GaAs are contaminated with silicon atoms from the quartz growth tube and this renders them n-type. This is not a problem if highly doped n-type material is required, as extra Si will be added to the melt anyway. Although there are few uses for p-type bulk GaAs, the over-doping of the melt with an acceptor species (usually Zn) effectively renders the crystal p-type. The reduction in hole mobility by compensation of a minority of the Zn atoms by the Si atoms is of little consequence.

However, the advantages of **SI** behaviour can only be obtained after the Si donors have been counter-doped

by the incorporation of Cr atoms in the melt [23.12, 13]. Chromium atoms act as deep acceptor centers in n-type GaAs and act to pin the Fermi energy just above the mid-gap, see Fig. 23.5. The GaAs so produced exhibits a resistivity that can exceed $10^8 \Omega\text{cm}$. Such Cr-doped GaAs was the mainstay of the high-speed GaAs device industry for over a decade, but growth problems, from the low segregation coefficient and solubility of Cr, resulted in low wafer yields, making the substrates expensive. Device fabrication problems from the rapid out-diffusion of Cr from the substrates into devices, resulting in lower speed, unacceptable device characteristics and device instability, also became evident.

Finally, the combination of poor thermal conductivity and low critically resolved shear stress (CRSS) at elevated temperatures results in inevitable thermal gradients in the cooling crystal producing plastic deformation by the creation of slip dislocations. In **HB** and horizontal **GF** material the dislocation densities are around 10^3cm^{-2} [23.14], although these densities can be reduced by over an order of magnitude due to *impurity hardening* in highly n-type GaAs [23.15]. Dislocations, their generation and their properties will be considered later.

23.1.3 Liquid-Encapsulated Czochralski (LEC) Technique

General Considerations

The Czochralski technique, in which a crystal is pulled from a melt, was originally used for metals and was then modified for the commercial growth of Ge and then Si. The rotation of the seed and crystal results in the immediate advantage of producing boules of circular cross section. Simultaneous rotation of the melt can result in efficient mixing of the host and dopant, a great advantage for doped crystals. In the case of compounds, where the partial pressures of one or both components are large, the melt surface must be protected either by incorporating an independent source of the vapour under dissociation (as in **HB** or **GF** growth) or by other means. In **LEC** growth, the surface is covered by an encapsulant layer of liquefied boric oxide, B_2O_3 [23.16, 17]. The axially rotating crystal is withdrawn through the encapsulant and then cools naturally by heat radiation, and by conduction and convection via the high-pressure ambient gas, see Fig. 23.7.

LEC pullers are high-pressure growth machines (and, therefore, expensive) because the internal pressure can exceed several atmospheres, especially when the Ga and As are compounded. In the growth of a compound

Fig. 23.7 LEC growth. The dark-grey arrow indicates the liquid–solid interface where growth takes place. As the growing crystal is pulled through the molten boric oxide it is rotated, resulting in a cylindrical boule. The boat is rotated in the opposite direction to stir the melt efficiently. (Courtesy Wafer Technology plc. UK)

like GaP, the internal pressures can exceed 100 atm. The boric oxide liquefies at temperatures of a few hundred degrees Celsius and floats to the surface of the other materials in the crucible. At all times during the subsequent reaction and growth it protects the surface from As loss. It also acts to purify the melt, probably because of the oxidising behaviour of its water content [23.18]. If the crucible is quartz, the resulting, nominally undoped, crystal is n-type because of Si incorporation. However, if the crucible is made from pyrolytic boron nitride (pBN) the crystal is SI over its entire length even without the introduction of Cr into the melt [23.19] (Sect. 23.1.3).

Nearly all LEC GaAs is contaminated by boron at concentrations up to 10^{18} cm^{-3} [23.20]. In all SI material these B atoms take up Ga lattice sites and are electrically inactive [23.21]. In Si-doped GaAs some of the B atoms appear to be incorporated as an acceptor species [23.22].

The automated growth of near-cylindrical crystals of accurately defined diameter would make LEC the choice of growth if it were not for the high dislocation density found in all but the highest carrier concentration n-type GaAs (this exception being a result of impurity hardening). Uncontrolled cooling of the LEC crystal causes the outside to contract on to the core, creating slip dis-

locations at densities of 10^4 – 10^5 cm^{-2} [23.23]. This defect creation occurs at temperatures just below T_m where dislocation motion by slip is easy. In addition, high concentrations of native point defects, which allow dislocation motion by climb, are also present. As a result, the dislocations are able to polygonise into cells, a rearrangement that reduces their strain energies. The final arrangement of a dislocation cell structure is the situation that is usually seen when a wafer is assessed.

As in HB and horizontal GF growth, the crystal can be doped n-type or p-type. Si or Te are normally used for n-type doping while Zn is used for p-type material. As mentioned above, an unfortunate reaction between the melt and the boric oxide has been found to occur with Si doping, leading to a reduction in Si uptake and considerable boron acceptor contamination of the GaAs [23.24]. In many cases, the concentration of B in the final crystal is comparable to the Si concentration. Nevertheless, Si remains one of the preferred donors for LEC GaAs.

LEC growth is controlled by computer and crystals of mass up to 20 kg and diameter up to 200 mm are easily produced. Wafers of 150 mm diameter are routinely supplied to device manufacturers from LEC crystals: at the time of writing this article 200-mm-diameter wafers were being made available to manufacturers for assessment.

Growth of SI LEC GaAs

The growth of nominally undoped GaAs by LEC from a pBN crucible results in SI behaviour. Chemical analysis of this type of GaAs always finds a concentration of carbon that is higher than the total concentrations of all other electrically active impurities [23.21]. The high carbon concentrations are not too surprising because not only is carbon a possible impurity in both Ga and As but there are many components of the LEC puller, namely the heaters and much of the thermal insulation, which are also made of carbon. Much work has shown that the carbon is introduced to the Ga–As melt through the gas phase, probably as carbon monoxide and the control of the partial pressure of this gas can be used to control the uptake of carbon in the crystal [23.25]. Because carbon atoms take up As sites and act as shallow acceptors, the resulting crystal would be expected to be p-type.

Some of the carbon acceptors are compensated by residual concentrations of shallow donors such as silicon and sulphur. The compensation of the rest of the carbon acceptors is performed by a native deep donor species, EL2, which pins the Fermi Energy close to the mid-gap. However, the final resistivity of the GaAs depends mainly on the carbon concentration [23.26]. The

atomic identity of EL2 was a hot topic of research for many years and there still remain questions as to its identity [23.27]. However, what is not questioned is that the defect involves the As-antisite defect, As_{Ga} .

After growth, high concentrations of EL2 are found associated with dislocations and this results in nonuniformities in electrical properties [23.28, 29]. Micro-precipitates of hexagonal As are also found in close association with the dislocations [23.30]. Most manufacturers use ingot anneals to render EL2 concentrations more uniform and to improve electrical uniformity [23.31]. Some follow ingot heat treatments with anneals of the individual wafers [23.32]. The schedules of these treatments vary between wafer suppliers but, in general, after these treatments the resistivity is of the order of $10^7 \Omega \text{ cm}$ with a uniformity of better than $\pm 10\%$.

It must be emphasised that the dislocation density cannot be reduced by heat treatments and the needs of device manufacturers for material of lower dislocation density has led to the development of improved growth techniques, the one now in general use being the vertical gradient freeze (VGF) method.

23.1.4 Vertical Gradient Freeze (VGF) Technique

This is a modification of the horizontal technique where the melt is contained in a vertical crucible above a seed crystal. The crucible, surrounded by the furnace, is pBN if SI GaAs is to be grown; otherwise, it can be quartz. The growth proceeds from the bottom of the melt upwards until the melt is exhausted [23.33]. Because cooling is better controlled, the resulting temperature gradients are much reduced compared to the LEC method, resulting in crystals with lower dislocation densities, typically $10^2\text{--}10^3 \text{ cm}^{-2}$. A schematic of VGF method is shown in Fig. 23.8.

The starting material is polycrystalline GaAs. Often, this can be synthesised from the elements in a LEC puller before being withdrawn rapidly from the crucible. This is a useful way of employing a LEC puller that might otherwise be redundant. The LEC puller also allows the introduction of a controlled amount of carbon, which will be necessary for SI behaviour in the final ingot. The use of polycrystalline GaAs starting material means that the VGF equipment can be easily fabricated in-house, as

Fig. 23.8 VGF growth. The seed crystal, in the narrow section at the bottom of the crucible, is held below the melt and the growth takes place upwards. The *solid arrow* indicates the solid–liquid interface where growth takes place. The boric oxide surrounds the liquid and solid and helps in the final extraction of the cooled crystal from the crucible. (Courtesy Wafer Technology plc. UK)

high pressures will not be experienced. Boric oxide can be used to encapsulate the melt and to ease crystal removal from the crucible but the sealed system will ensure that the melt remains nearly stoichiometric [23.34].

Initially the major drawback to VGF was the low growth rate coupled with the inability to see the progress of the growth. In other words, if growth was not progressing correctly, this could not be detected until after the entire melt was solidified and this was several days in most circumstances. However, after the method is optimised the yield can approach 100%. The usual dopants can be employed if conducting material is required.

The reduced dislocation density in VGF GaAs has made it the material of choice for most applications and especially in optoelectronics, where dislocations are particularly deleterious to performance as they act as nonradiative recombination paths. At the time of writing, SI wafers of 200 mm diameter have been supplied as test wafers to device manufacturers.

Readers who require a recent and more thorough discussion of the growth of GaAs from the melt are referred to [23.35].

23.2 Epitaxial Growth of GaAs

Very few devices now use melt-grown GaAs in their active parts. Instead, they rely on the substrate to act as support for complex structures that are grown on the surface. These will typically employ ternary or even quaternary alloys. The former are the most important and are exemplified by the $\text{Ga}_{1-x}\text{Al}_x\text{As}$ alloys, all of which have a very similar lattice constant as GaAs, varying from 5.6533 Å for GaAs to 5.6605 Å for AlAs. Selected electrical and optical properties of these alloys are presented in Fig. 23.9.

These alloys are in the form of thin layers which must have an accurately controlled composition, lattice-match the substrate, have accurate doping and, most of all, a well-defined layer thickness, often of only a few hundred nm. Growth of a new material on to a substrate where the atomic planes accurately line up is *epitaxial*. In this section, we present four approaches to the epitaxial growth of GaAs, the first two being more of historical than practical interest.

23.2.1 Liquid-Phase Epitaxy (LPE)

In **LPE**, the GaAs layer to be deposited is formed by first dissolving GaAs and the dopant into a liquid, usually Ga, at elevated temperatures, normally around 800 °C [23.37]. The solubility of GaAs in Ga is 3×10^{-3} mass fraction at these temperatures but it falls rapidly if the temperature is reduced. This behaviour can be seen in Fig. 23.3. Thus, if the Ga melt is saturated at a high temperature and is placed over the substrate, GaAs will be deposited as the temperature is reduced. Dopants added to the Ga melt will also be introduced into the growing GaAs layer, allowing junctions to be fabricated. If the melt is replaced by a molten (Ga + Al) alloy, a layer of GaAlAs can be grown, also with doping.

LPE usually uses several pots of molten metal (Ga or Ga + Al, for example) in a high-purity graphite, slider system. These can be moved over the substrate in turn to allow the growth of consecutive layers. A figure of a sliding-boat **LPE** reactor is shown in Fig. 23.10.

Advantages of **LPE** include the high crystalline purity of layers especially in terms of low concentrations of native point defects. Disadvantages are associated with the control of growth. It is difficult to produce reliably flat layers as convection currents in the liquid metal tend to produce a rippled surface. The thickness often

Fig. 23.9a,b Compositional dependence of some important properties of AlGaAs . **(a)** shows the dependence of the band-gap energy on composition. Below 45% Al, the alloy has a direct band-gap energy that increases steadily with Al composition. However, above 45% the band gap becomes indirect and the band-gap energy of pure AlAs is only 2.168 eV. **(b)** The refractive index of the AlGaAs alloys shows no dependence on the band-gap type and decreases steadily from a value of approx. 3.6 (GaAs) to 2.97 (AlAs), both these values being wavelength-dependent. (After [23.4])

Fig. 23.10 **LPE** growth using the slider system. The Ga melts saturated with GaAs and dopants are sequentially placed over the GaAs substrate allowing several epitaxial layers to be grown. (After [23.36])

increases towards the periphery of the substrate and it is difficult to produce large areas of constant thickness. **LPE** was important for the **LED** and laser industry in early years but it is now rarely used for GaAs.

23.2.2 Vapour-Phase Epitaxy (VPE) Technologies

Chloride and Hydride Growth

In **VPE**, the components of the layer to be grown are transported to the substrate surface in the form of gases.

In chloride and hydride growth, the As vapours are AsCl_3 and AsH_3 , respectively, both of which are converted to gaseous As_4 in the growth reactor. The volatile Ga component is GaCl produced by passing HCl gas over a well containing heated Ga metal. This takes place near 850°C . The volatile Ga and As components are reacted with H_2 over the GaAs substrate, which is held near 750°C . A two-zone furnace is therefore required. The growth rate can be up to $20\ \mu\text{m}$ per hour. Dopants can be introduced as chlorides. Full details of these growth techniques have been reviewed by Somogyi [23.38].

The major commercial use for these growth methods is for the fabrication of $\text{GaAs}_{1-x}\text{P}_x$ LEDs, see Fig. 23.11.

Fig. 23.11 The hydride growth method. A vertical system is shown but horizontal methods are also used. The volatile gallium chloride GaCl is produced near 850°C , and growth takes place near 740°C . The rotating sample holder ensures that the growth on several substrates is uniform and reproducible. (After [23.36])

Phosphorus can be introduced as PCl_3 or PH_3 and the growth is sufficiently fast that grading from pure GaAs to the required alloy can be performed in a reasonable time by varying the ratio of AsCl_3 to PCl_3 partial pressures. Unfortunately, modern device technologies rely heavily on alloys from the GaAs/AlAs system and growth of AlAs is not possible using these methods because no chloride of Al is sufficiently volatile.

Metalorganic Chemical Vapour Deposition (MOCVD)

In **MOCVD**, sometimes known as metalorganic vapour-phase epitaxy (**MOVPE**), the gaseous As precursor is AsH_3 and the volatile metal sources are alkyls (sometimes known as metalorganics) such as trimethyl-gallium (**TMG**), $\text{Ga}(\text{CH}_3)_3$, although others have been used. Trimethyl-aluminium (**TMA**), $\text{Al}(\text{CH}_3)_3$, is used for the Al component of the alloy and trimethyl-indium (**TMI**) is used for the In component.

For p-type material the usual acceptor is Zn in the form of diethyl zinc, $\text{Zn}(\text{CH}_3)_2$. Si is the most commonly used donor in the form of silane, SiH_4 .

All the alkyls are volatile liquids at room temperature and are kept refrigerated in order to reduce and control their vapour pressures. AsH_3 and SiH_4 are gases and are supplied diluted in hydrogen.

The alkyls are released from their cylinders by bubbling high-purity hydrogen through them. They are then introduced to all the other constituents with more hydrogen at room temperature. The reaction to produce the layer only occurs when the vapours are passed downstream over the heated substrate. This is held at approximately 750°C for GaAs growth but is somewhat higher for AlGaAs. Figure 23.12 is a schematic of a **MOCVD** apparatus.

This technique has been discussed in detail [23.39, 40]. Once the control of the gas flow over the heated substrate has been optimised, layers can be grown with great ease and with great accuracy, the layers being of high crystalline quality, and of good uniformity in both constitution and thickness. The growth of alloys of different composition or material with varying dopant concentration can be simply performed by changing the hydrogen flow rate through the alkyls or dopant sources using mass-flow controllers.

Note that SI epitaxial GaAs cannot be obtained unless Cr is added during growth or lightly p-type GaAs is grown and a post-growth anneal to generate EL2 centres is undertaken. Both methods have been reported, (see [23.41–44] for further details).

Fig. 23.12 MOCVD growth. Separate mass-flow controllers and valves control the hydrogen flow through each of the alkyl liquids, which are held in cooled, sealed flasks. The metalorganic vapours are introduced to the substrate with arsine. The substrate is heated by an induction furnace via a graphite susceptor that supports the substrate as well as coupling to the field of the RF field to produce heating. The gaseous silane is for n-type doping

In a research laboratory, the growth equipment can be built in-house and a skilled operator can control the growth of single samples. Commercially the equipment is much more complicated, with several substrates being processed together and the entire growth procedure being computer-controlled. Manufacturers put much effort into ensuring that the gas flow over each substrate is as uniform as possible to ensure reproducible growth. Early problems with difficulties in obtaining alkyls of satisfactory and reproducible quality have been solved.

However, a limitation of MOCVD concerns the rate at which a layer composition can be changed. The abruptness of the interface between layers can be critical in many modern applications and this is often limited in MOCVD by mixing of the gas upstream from the substrate. Thus, even if the mass-flow controllers that control the rate at which hydrogen bubbles through the alkyls change their relative concentrations instantly, there will be some mixing in the upstream gases which will cause this change to be more gradual when the gases flow over the substrate. This causes a slight grading in the grown interface and this can be deleterious to some devices. Nevertheless, most of current GaAs-based devices are produced commercially by MOCVD.

Unfortunately, all the precursors used for MOCVD are poisonous, with AsH_3 being extremely so. Moreover, satisfactory growth requires a surplus of AsH_3 over the alkyls of about ten to one in atomic concentrations to be present. It follows that the exhaust gases

Fig. 23.13 MBE growth takes place in a UHV chamber. Each component of the required epitaxial layer is supplied by an effusion cell (also known as a Knudsen cell) and shutter. The substrate is held on a heated, rotating holder. Cryopanels cooled by liquid nitrogen help to keep the base pressure of the system to about 10^{-11} Torr. The RHEED gun and associated fluorescent screen allow the growth process to be monitored continuously. Substrates are positioned on the sample block via the buffer chamber where they have been previously prepared

are As-rich and very toxic. MOCVD equipment requires considerable exhaust gas cleaning and this makes the technique rather demanding in terms of effluent processing.

23.2.3 Molecular-Beam Epitaxy (MBE)

At its simplest, MBE is a high-purity growth technique where all the components of a required material are evaporated as elemental beams. The term molecular reflects the observation that some elements evaporate as molecules. As an example, under MBE growth conditions arsenic vapour is primarily in the form of As_4

molecules. The beams are incident on a heated, rotating substrate where they react to form a growing layer [23.45].

In practice, the growth takes place in an ultra-high-vacuum (UHV) chamber at a base pressure of about 10^{-11} Torr. The sources are usually high-purity elements held in Knudsen cells (high-vacuum effusion cells). The molecular beams are controlled by simple metal shutters that can be moved rapidly in and out of the beams by external drives. A typical MBE reactor will have up to eight such sources, some for the components of the host semiconductor, Ga, Al, etc. and others for dopants, each held at the relevant temperature to produce a molecular beam of the correct effective pressure, see Fig. 23.13.

The use of UHV technology allows the use of in situ analysis of the growth to be monitored and this has provided much information on details of the growth mechanisms. A favourite tool is reflection high-energy electron diffraction (RHEED) whose use gives important information regarding the quality of the growth with single atomic layer sensitivity.

The advantages of MBE include the use of high-purity elemental sources rather than compounds (whose purity is less controllable). The use of moveable shutters in front of each cell means that each source can be turned on or off in a fraction of a second. As a result, MBE-grown material can be of very high quality with the sharpest interface abruptness. These qualities are essential in several microwave devices and this is one of the major commercial uses for MBE. However, MBE has been a favourite growth technique for semiconductor research laboratories because it is well suited for the small-scale growth of specialised structures.

As an industrial technique, MBE suffers from several problems. The first results from its reliance on UHV technology, meaning that it is expensive to install, requires large quantities of liquid nitrogen to keep cold, considerable power to keep under vacuum, and special clean rooms. It is expensive to operate. Conditions for correct growth include a beam effective pressure ratio of As to group III metals of about six. As a result, the inside of the machine becomes coated with arsenic, making it very unpleasant to clean. Replenishing the cells when they are exhausted can be a slow and difficult process because recovery of the vacuum after the inside of the machine is exposed to atmospheric gases can take several days.

There are three modes for MBE growth: normal, low temperature and gas source.

Normal MBE Growth

In conventional MBE [23.46], the growth normally takes place at around 600°C with an As_4 flux that is considerable greater than the Ga flux. Often the beam effective pressure (BEP) ratio of As to Ga is around six. The Ga flux controls the growth rate and a Ga flux of $6 \times 10^{14} \text{ cm}^{-2} \text{ s}^{-1}$ produces a growth rate of one monolayer per second.

The GaAs so produced is of excellent structural and electrical quality. It is usually doped n-type with Si but Se and Te are often used. Unlike melt-grown GaAs, there is little auto-compensation and doping levels exceeding 10^{19} cm^{-3} can be obtained; p-type doping is normally achieved using Be, although for some devices carbon is preferable. These acceptors can be incorporated at concentrations exceeding 10^{20} cm^{-3} . AlGaAs alloys are grown by opening the shutter of an Al cell. Growth proceeds at a somewhat higher temperature but with similar ease. Should AlGaAs alloys of different composition be required, it is usual to have two Al cells at different temperatures and these are opened as required. For similar reasons a device structure with different n-type doping regions such as a metal–semiconductor field-effect transistor (MESFET) or high-electron-mobility transistor (HEMT) will require the use of at least two Si cells at different temperatures. These means of changing material composition increase equipment complexity and cost.

Low-Temperature MBE (LTMBE) Growth

Unlike the VPE techniques presented previously, MBE growth can proceed at temperatures as low as 200°C , in a regime called low-temperature MBE (LTMBE), see [23.47, 48]. One reason for this is that no chemical reactions are needed to release the elemental Ga and As on the GaAs surface from gaseous precursors (although the As_4 must be dissociated) and there is sufficient surface atomic mobility at these low temperatures to ensure uniform, crystalline growth. At these low growth temperatures and under standard As-rich growth conditions with a BEP ratio of greater than 3, undoped GaAs is very As-rich, with up to 1.5% excess As, contains high concentrations of point defects and is high resistivity. This material is heat-treated before use to improve its properties and stabilise it. Growth of LTMBE GaAs under less As-rich conditions, or at higher temperatures, results in nearly stoichiometric material. In all cases, however, SI behaviour is observed.

The real advantage of annealed LTMBE GaAs to device manufacturers is the extremely low minority carrier lifetime of $< 0.5 \text{ ps}$. This makes it useful in the fabrica-

tion of ultrafast optodetectors [23.49] and as a substrate for high-speed integrated circuits (ICs) [23.50].

Gas-Source and Metalorganic MBE

In modifications known as gas-source MBE (GSMBE) and metalorganic MBE (MOMBE), some sources that are volatile at room temperature are used.

In GSMBE, AsH₃ replaces the metallic As source and some dopants are also replaced by volatile sources. One of the advantages of GSMBE is the virtually unlimited source of As (from a high-pressure gas bottle) and the ease of replacing it and similar group V sources. These are exhausted rapidly in normal growth because of the need to use an excess of these elements.

In MOMBE the group III metallic sources are replaced by metalorganics like TMG. By using a combination of triethyl-gallium (TEG) and TMG, MOMBE growth can lead to the controlled incorporation of carbon acceptors at concentrations up to 10^{21} cm^{-3} , necessary for heterojunction bipolar transistors (HBT) fabrication (see later) and for other uses where stable, highly p-type GaAs is required. Similar ease of carbon incorporation in GSMBE uses CCl₄ or CBr₄ as sources. A thorough review of these techniques has been given by Abernathy [23.51].

23.2.4 Growth of Epitaxial and Pseudomorphic Structures

The epitaxial growth of GaAs on GaAs is one of the simplest epitaxial growth processes where, if the growth is performed correctly, analysis of the resultant structure will show no break in the atomic planes at the substrate-layer interface. Because the lattice constants of the ternary GaAlAs alloys match that of GaAs, the growths of these are also simple in principle and are the basis for many devices.

Attempts to grow layers with lattice constants that are dissimilar to the substrate result in the incorporation of misfit dislocations. Although these are initially parallel to the interface, they are deleterious to device

performance because their interactions can cause them to orient themselves in the growth direction and to invade the electrically active structure above. They can then act as recombination centres. However, even when a required ternary does not lattice-match the substrate two approaches can be used to give satisfactory device results; grading and pseudomorphic growth.

In grading, the material composition, and hence the lattice constant, is changed gradually from that of the substrate to that of the required alloy. Misfit dislocations are still produced but they are now distributed on many lattice planes and they tend not to interact. This restricts them to the graded region and away from the active regions above. Grading is used for the production of low-cost visible LEDs based on GaAs_{1-x}P_x. These devices can be formed on either GaP or GaAs substrates according to the required alloy composition (which controls the colour) and growth by the hydride or chloride process allows grading to be performed. Other uses for grading occur in the production of optical confinement layers in certain types of lasers (Sect. 23.13).

Theoretical calculations show that mismatched growth does not result in the immediate creation of misfit dislocations, because there exists a critical thickness below which the strain energy is insufficient to produce them [23.52]. If growth is stopped at this stage, the layer remains dislocation-free. Indeed, if a layer of the substrate compound now covers the layer, the structure is further stabilised. Its enforced lattice match to the substrate strains the mismatched layer; if it would normally be cubic, the epilayer assumes a tetragonal structure, with the *c*-axis aligned in the growth direction. This distortion produces electrical and optical properties that are no longer isotropic. In other words, properties parallel to the growth interface are different to those perpendicular to it. Often these offer advantages over the cubic material. This type of growth is called pseudomorphic and is very useful in several microwave devices. Pseudomorphic structures can be grown by MOCVD or MBE, although the latter is usually preferred.

23.3 Diffusion in Gallium Arsenide

Diffusion, which refers to the motion of impurity atoms under a concentration gradient, can be a positive or negative process. As an example of the first category, diffusion can be used to introduce impurity atoms into the bulk of a solid. This is the most important process in Si technology, for example. Diffusion is also

one of the atomic processes that are thought to be important in making effective Ohmic contacts. However, diffusion is also the mechanism by which large concentration gradients grown in to a structure can relax and cause degradation to the characteristics of the device.

Tuck has written excellent reviews of atomic diffusion in semiconductors [23.53, 54]. For various reasons, the diffusion characteristics of most impurities in GaAs are only poorly understood. In this section, we present a short summary of those diffusion parameters that are well understood or are important in GaAs.

Diffusion is a high-temperature process resulting from the random motion of the impurity atoms within the host matrix. The process is described by the two Fick's laws.

The first law states that the flux of diffusing atoms J in a given direction, say x , is proportional to the concentration gradient along x or $J = -D(\partial C/\partial x)$. The negative sign shows that the net motion of atoms is in the opposite direction to the concentration gradient. This law can easily be proved by atomic models. The constant of proportionality D is the diffusion coefficient and is a strong function of temperature T according to $D = D_0 \cdot \exp(-E/kT)$, where E is an activation energy for the process and D_0 is a pre-exponential function, the diffusion constant.

There are two simple diffusion mechanisms. The first is the *substitutional* mechanism where impurities on a sublattice (Ga or As) move by jumping into adjacent vacant lattice sites. E has two components which add: an energy to move from one site to another, the migration energy, E_m , and a further *energy of formation* to produce the vacancy, E_v . This results in a large value of E and slow diffusion, normally undetectable at diffusion temperatures under a few hundred degrees Celsius below the melting temperature. The second is the *interstitial* mechanism where impurity atoms in interstitial sites move by jumping into adjacent interstices. Here E has a single component, the migration energy, of a value close to E_m . This results in a small value of E and rapid diffusion. Interstitial diffusion can often be observed at low temperatures, in extreme cases at or below room temperature.

The second law represents conservation of mass and states that the rate at which a concentration changes in a given volume, $\partial C/\partial t$, is equal to the difference in input and output fluxes from the volume. Combination of the two laws, for a value of D that does not depend on concentration, results in the diffusion equation, $\partial C/\partial t = D(\partial^2 C/\partial x^2)$. Solutions to this equation have been calculated for many situations including those that are of experimental interest [23.56]. When experimental diffusion profiles do not match theoretical predictions, it must be concluded that D is a function of C .

Experimental investigations usually start with coating the surface of a GaAs sample with the impurity.

Fig. 23.14 Experimental diffusion profiles for Zn in GaAs at 1000 °C with excess arsenic in the ampoule. Diffusion times: A: 10 min, B: 90 min, C: 3 h, D: 9 h. (After [23.55])

The GaAs is heated rapidly to temperature T and held at T for a known time. The GaAs is then cooled rapidly. Concentrations of the impurity as a function of depth are then determined, either by using radiotracer methods (if the impurity can be tagged with a relatively long half-life isotope), by secondary-ion mass spectrometry (SIMS) if this technique is available, or electrically if the impurity is electrically active at room temperature.

Diffusions at different temperatures can be compared via an Arrhenius plot to derive the activation energy E . Diffusions from a thin layer are expected to result in a smooth, exponential profile. Other diffusion conditions result in profiles of different forms [23.53]. It is necessary to consider the loss of As from the GaAs at elevated temperatures when undertaking this procedure and a little elemental As is often added to the diffusion ampoule to replace loss from the surface. Other complications include possible chemical reactions between the impurity and either Ga or As, or both, which can result in severe changes to the experimental conditions. For these reasons, many diffusion measurements quoted in the literature may be quite inaccurate.

23.3.1 Shallow Acceptors

The first impurity whose diffusion profile in GaAs was carefully analysed was zinc because it was by diffusion of Zn into n-type GaAs to make a p–n junction that early LEDs were fabricated. When Zn is diffused into GaAs (Fig. 23.14) the profile is found to be deeper than expected for a substitutional mechanism. Moreover, it is not exponential but exhibits a concave shape with a very abrupt diffusion front.

Electrical evaluation reveals that, after diffusion, nearly all the Zn atoms act as shallow Zn_{Ga} acceptors. Interpretation suggests two possible *interstitial–substitutional* diffusion mechanisms, both of which involve the diffusion of singly positively charged interstitial Zn atoms, Zn_i^+ , which take up Ga lattice positions to become substitutional Zn_{Ga}^- acceptors. Either of these models suggests that D is proportional to $[\text{Zn}_{\text{Ga}}^-]^2$.

Under certain circumstances, the diffusion of Mn, which is a shallow acceptor, Mn_{Ga} , can be very similar to Zn. However, surface reactions cause experimental problems so that data is not so consistent.

Be_{Ga} is an acceptor often used in MBE growth. Its diffusion behaviour is poorly investigated but it has been concluded that D is concentration-dependent. Rapid ageing characteristics of GaAs/AlGaAs heterojunction bipolar transistors (HBTs) have been attributed to diffusion of Be from the highly p-type base into the emitter and collector regions [23.57].

C_{As} is a shallow acceptor and is important in Si GaAs as well as in MBE growth. It seems to be a very slow diffusing species, probably via purely substitutional diffusion. The diffusion rate depends on whether the GaAs is As- or Ga-rich, being greater in the former case. Arrhenius plots give expressions for D as $0.110 \exp(-3.2 \text{ eV}/kT)$ and $2.8 \times 10^{-4} \exp(-2.7 \text{ eV}/kT) \text{ cm}^2 \text{ s}^{-1}$, respectively. Carbon diffusion in GaAs has been reviewed by Stockman [23.58].

23.3.2 Shallow Donors

All shallow donors of scientific interest, group IV atoms occupying Ga or group VI atoms occupying As lattice

sites, are slow substitutional diffusers whose measurement has posed considerable problems [23.54]. Donor diffusion appears neither to have any direct technical application nor to be involved in any device degradation, although it is expected to be involved with the creation of good Ohmic contacts to n-type GaAs. A recent assessment of Si diffusion in GaAs using SIMS to trace the motion of the Si atoms has been reported in [23.59].

In general, it is observed that atoms occupying the group V sublattice are generally very slow diffusing, possibly a result of the high energy of formation of V_{As} .

23.3.3 Transition Metals

Transition metals normally occupy Ga lattice sites and act as deep acceptors. Cronin and Haisty [23.12] grew GaAs crystals doped with virtually all the first series of transition metals and were the first to observe their acceptor properties. This investigation showed that Cr doping produced SI material. However, most of these metals are very rapid, interstitial diffusers in GaAs, although their final situation is substitutional, and this has led to their almost total disuse from GaAs technology.

As an example, diffusion of Cr has been investigated by several groups, (unfortunately, with disparate results). Diffusion into GaAs from a surface source (indiffusion) produces diffusion rates that are larger than those from within the host lattice. However, there are clear surface effects that result from a chemical reaction between Cr and GaAs. After diffusion the profile is deep, indicating interstitial diffusion, but nearly all the Cr atoms seem to act as acceptors, i. e. they are substitutional [23.54]. Thus, there are similarities with the earlier case of Zn diffusion. This interstitial–substitutional diffusion is probably common in GaAs, although details are rare. One case where some justification for this mechanism was obtained was the case of Fe diffusion. Here, electron paramagnetic resonance (EPR) studies of the diffused layer showed good agreement between $\text{Fe}_{\text{Ga}}^{3+}$ and the atomic concentration of Fe determined by radio-tracer measurements although the rapid penetration rate strongly indicated interstitial diffusion [23.60].

23.4 Ion Implantation into GaAs

Modification to the electronic properties of the near-surface region of a semiconductor is the basis of nearly all devices. In Si this is routinely performed by diffusion or ion implantation. However, most microwave

GaAs devices that require this modification are n-type devices such as metal–semiconductor field-effect transistors (MESFET) and, as mentioned previously, diffusion of shallow donors into GaAs is not technically

possible. MESFETs are majority carrier, n-type conduction devices that are fabricated on the surface of SI GaAs. They need abrupt depth profiles of two carrier concentrations (Sect. 23.11.2 for more details). In ion-implanted MESFETs, these regions are produced by direct implantation of donor atoms into the surface. The depth profile of implanted ions can be calculated using computer programs. In general, the greater the energy of the ion, the greater is the mean penetration and the greater the mass of the ion, the lower the penetration.

Unfortunately, damage to the host crystalline structure is associated with the implantation, resulting in zero electrical activity from the implanted ions. This damage must be repaired by thermal annealing. Two types of anneal schedule are used, furnace annealing and rapid thermal annealing (RTA). The first entails heating the GaAs in a conventional furnace at 850–900 °C for at least 15 min. RTA uses a higher temperature of 900–950 °C but for times of only approximately ten seconds. In each case the surface must be protected by an impervious layer to stop the loss of As. This is

often silicon nitride (Si_3N_4) but the simple expedient of annealing two wafers face to face will reduce As loss to insignificant amounts. The recovery of electrical activation, being a thermally activated process, has an associated activation energy that is usually less than 1 eV. Because that for diffusion often exceeds 2.5 eV, careful implant annealing does not result in appreciable diffusion. A full list of these parameters is given in the article by Sealy [23.61].

In Si, implant anneals remove nearly all this damage; in GaAs only a fraction of the implant damage can be removed, especially after high implant fluences, unless the heat treatments are applied for times and temperatures that are incompatible with device manufacture. Anneals of acceptor-implanted GaAs are more effective with nearly 100% activation of the implant being achievable. The inefficient activation of donor implants in GaAs is not fully understood.

Applications of ion implantation, mostly reserved for MESFETs and monolithic microwave integrated circuits (MMICs) based on MESFETs, are discussed later.

23.5 Crystalline Defects in GaAs

Crystal defects are crucial in determining many electrical and optical properties of GaAs. Most of these defects are incorporated during growth into melt-grown (sub-

strate) material but they can also be introduced in later processing steps.

23.5.1 Defects in Melt-Grown GaAs

Structural Defects

Previously, the problems associated with melt growth were introduced. The growing crystal, cooling from the outside, experiences compressional stresses that cause plastic deformation by the introduction and subsequent motion of dislocations.

In SI GaAs the polygonised dislocation structure is complex. Such structure is best revealed by specialised chemical etching of the surface to reveal dislocation arrangements [23.62, 63] or reflection X-ray topography [23.64]. Each technique reveals classical dislocation cells, *lineage* (the boundary between sections of the crystal that have a small tilt misorientation and caused by dislocation motion) and slip. The lineage occurs preferentially along the (110) diameters. A typical image from a 20-mm² area from a 3-inch-diameter (001) SI LEC GaAs is shown in Fig. 23.15.

The use of selective etching by molten alkalis is commonly used by substrate manufacturers in order

Fig. 23.15 A 20-mm² area of a 3-inch-diameter {001} SI LEC GaAs after etching to reveal dislocations. Many of the dislocations are arranged in a cellular wall formation enclosing regions where the dislocation density is small. The nearly vertical line, closely aligned along [110] is lineage where dislocations have interacted to produce a small-angle tilt boundary. (Courtesy of D. J. Stirland)

to reveal dislocations passing through the surface and being revealed as pits. Thus, they obtain an *etch pit density* (EPD), which corresponds to the dislocation density [23.65]. However, transmission electron microscopy (TEM) is a preferable, though much slower, method for investigating dislocations [23.66].

VGF GaAs contains a much lower density of dislocations but even these are found to be in the form of a cell structure [23.68]. n^+ -GaAs is much less dislocated and no cell structure is present. It is thought that the slip velocity of dislocations on their glide planes is reduced in highly n-type material, so that n^+ -GaAs contains far fewer dislocations than SI or p-type material. However, this cannot be the only reason for this hardening process as the addition of neutral atoms such as In at high concentration can also reduce the dislocation density to near zero [23.69]. The dislocation structures also contain microscopic precipitates, which have been found to be hexagonal, elemental As [23.30, 70]. These are absent in n^+ -GaAs.

Point Defects

SI GaAs is a relatively pure material. It contains boron impurities at high concentration but these are neutral (Sect. 23.1.2). Silicon and sulphur, both shallow donors, are found at concentrations of around 10^{15} cm^{-3} . Concentrations of other electrically active impurities are extremely low and can be ignored.

The exception is carbon, a shallow acceptor, which occurs naturally in LEC GaAs, but which is often added intentionally to VGF GaAs, at concentrations of $10^{14} - 10^{16} \text{ cm}^{-3}$. For this reason carbon must be treated as a dopant and not an impurity. The accurate measurement of the carbon concentration is challenging. The standard method uses the low-temperature far-infrared absorption due to the localised vibrational modes (LVM) of carbon acceptors, a technique that has a sensitivity of around 10^{14} cm^{-3} [23.71, 72].

However, SI GaAs contains many native defects, and these are listed in Table 23.2.

Most native point defects are deep donors, at concentrations of $10^{13} - 10^{14} \text{ cm}^{-3}$ with one, EL2, the As antisite defect (As_{Ga}), being dominant, existing at a concentration of $1 \times 10^{16} - 1.5 \times 10^{16} \text{ cm}^{-3}$. Compensation of the carbon acceptors by EL2 pins the Fermi level near the centre of the band gap, the other point defects being fully ionised by this process. The lack of native acceptors at concentrations above those of donors makes the presence of carbon (or other chemical acceptors) mandatory for SI behaviour.

The EL2 Centre

EL2 is a native deep double donor. Its first ionisation state is at 0.75 eV above the valence band. This is the level that controls the Fermi level in SI GaAs. A second ionisation from + to ++ occurs at an energy at

Table 23.2 Deep electronic levels observed in melt-grown SI GaAs. EL is an electron level and HL is a hole level. In most commercial material only EL2 exists at concentrations exceeding 10^{15} cm^{-3} and is the only deep level assumed to be involved in the compensation mechanism to give SI properties. (From [23.67])

Label	Origin	Concentration (cm^{-3})	Emission energy (eV)	Capture cross section (cm^2)
EL11			$E_c - 0.17$	3×10^{-16}
EL17			$E_c - 0.22$	1.0×10^{-14}
EL14			$E_c - 0.215$	5.2×10^{-16}
EL6	Complex defect	$10^{14} - 10^{16}$	$E_c - 0.35$	1.5×10^{-13}
EL5		$10^{14} - 10^{16}$	$E_c - 0.42$	10^{-13}
EL3		$10^{13} - 10^{15}$	$E_c - 0.575$	1.2×10^{-13}
EL2	Native defect As_{Ga} or $[\text{As}_{\text{Ga}} - \text{X}]$	$5 \times 10^{15} - 3 \times 10^{16}$	$E_c - 0.825$	1.2×10^{-13}
HL10		Below 2×10^{14}	$E_v + 0.83$	1.7×10^{-13}
HL9			$E_v + 0.69$	1.1×10^{-13}
HL7		1.7×10^{15}	$E_v + 0.35$	6.4×10^{-15}
"Ga _{As} "	Gallium antisite Ga_{As} or boron antisite B_{As}	$3 \times 10^{15} - 3 \times 10^{16}$ (dependent on Ga richness of melt)	$E_v + 0.077$ $E_v + 0.203$ (double acceptor)	

0.54 eV above the valence band. Only the singly ionised state is paramagnetic but EPR measurements on this state demonstrated that EL2 contained the As antisite defect [23.73].

EL2 exhibits a broad near-infrared absorption band in SI GaAs, which has been separated into components from neutral and singly ionised EL2 [23.74, 75].

EL2 has come under extreme scrutiny over the past two decades, not only because it results in SI behaviour, but also because it exhibits a remarkable photo-quenching property; at low temperatures EL2 defects can be excited into an inert metastable state by irradiating the GaAs with sub-band-gap light [23.74]. This process is associated with a photoactivated relaxation of As_{Ga} along a $\langle 111 \rangle$ direction into an interstitial site to produce a $[\text{As}_i - \text{V}_{\text{Ga}}]$ complex. Normal deep-donor behaviour is recovered by warming above 140 K [23.76, 77].

The two states of EL2 are shown in Fig. 23.16. Interestingly, a similar deduction about the motion of donors has been made in highly n-type GaAlAs when the Al content exceeds a critical value. The effect, which, results in the loss of normal donor behaviour, is ascribed to the generation of the DX centre. Thus, conduction electrons are lost on irradiating the cooled sample with sub-band-gap light. Like EL2 in GaAs, the recovery from DX-like behaviour is recovered by warming the sample.

High concentrations of EL2 are found in close association with dislocations in as-grown material. Coupled with the presence of As precipitates, this demonstrates that the environments of dislocations are very As-rich.

Fig. 23.16 The two states of EL2. The *spheres* represent As atoms. In T_d symmetry the central As atom is tetrahedrally bonded to four nearest neighbour As atoms as As_{Ga} . In the state represented by C_{3v} symmetry this As atom has been excited to move along the $\langle 111 \rangle$ direction where an uncharged metastable site is present. It is now represented by $[\text{V}_{\text{Ga}} - \text{As}_i]$. Heating above 150 K causes the As atom to return to the stable As_{Ga} structure. (After [23.27])

EL2 concentrations are rendered uniform by ingot anneals which, as expected, also improve the uniformity of electrical properties.

Concentrations of EL2 defects are easily determined by measuring their room-temperature infrared absorption at wavelengths near $1 \mu\text{m}$ [23.74]. In practice, EL2 concentrations are always $1.0 \times 10^{16} - 1.5 \times 10^{16} \text{ cm}^{-3}$ in crystals grown from a melt that is slightly As rich. The use of an infrared-sensitive closed-circuit television (CCTV) camera or photographic film can allow mapping of the concentrations to be made [23.78].

Another defect, often referred to as the *reverse contrast* (RC) defect can also be mapped. This must take place at lower sample temperatures but otherwise uses a similar technique [23.79, 80]. RC absorption also reveals dislocations. However, unlike EL2 concentrations, those of RC defects are not homogenised by these heat treatments, indicating that other point defects may also be resistant to standard anneal protocols. RC defects occur at relative concentrations that are the reverse to EL2 defects in unannealed material (they are high where $[\text{EL2}]$ is low, and vice versa) and seem to control minority carrier lifetime in SI GaAs and, thus, their low-temperature luminescence. Their identity as being As vacancies was demonstrated by positron-annihilation methods [23.81] and their nonuniform distribution was explained, at least in part, by the influence of dislocations on the As Frenkel reaction on the As sublattice as the crystal cools [23.82]. The identities of other point defects in SI GaAs have not been determined.

23.5.2 Epitaxial GaAs (not Low Temperature MBE GaAs)

Structural Defects

Because they cannot end within the crystal, dislocations that pierce the surface of the substrate must grow into the epilayer and, for devices that rely on minority carriers, this is a problem. The reason for this is that dislocations in GaAs can act as potent minority-carrier recombination centers. This may result from the presence of a high density of electrically active dangling bonds at the dislocation core. However, enhanced recombination from the presence of a relatively high concentration of point defects around the core (Cotterell atmosphere) cannot be totally ruled out. The latter would seem to be less likely in epitaxial GaAs because of the low growth temperatures and the low measured concentrations of these defects. However, the types of atoms that are expected to act as recombination centers are also expected to be rapid diffusers and their concentrations around dislo-

cations could be much greater than is estimated. The deleterious effects of these *threading dislocations* are the prime reason for the development of VGF and similar substrates.

Point Defects

Epitaxial GaAs contains a far lower concentration of intrinsic point defects than melt-grown material because of the low temperatures to which these materials are subjected. EL2 defects are found in epilayers grown by all the VPE techniques at concentrations up to 10^{14} cm^{-3} making it both the most common trap and the one occurring at highest concentration. Higher concentrations may be generated after growth by annealing at temperatures near 900°C . In this way, lightly p-type VPE GaAs can be rendered SI, see Sect. 23.2.2. A comprehensive list of electron traps has been presented in [23.83] and a similar list of hole traps has been presented in [23.84]. Capture cross-section determinations have been presented in [23.85].

In general, most point defects in epitaxial material are extrinsic and result from impurities present in the precursors or in the growth apparatus. In modern equipment, using purified starting chemicals, residual impurities are typically shallow donors such as Si and S that are difficult to remove. These produce a residual carrier concentration of around 10^{14} cm^{-3} in the best commercial, nominally undoped, epitaxial GaAs. There are notable exceptions to the high purity usually found in MOCVD and MOMBE GaAs

when carbon is used as a p-type dopant. Hydrogen can enter the growing layer and passivate the acceptors, see [23.86, 87], a case where intentional doping by one species can result in unintentional incorporation of an impurity, see also the previous case of Si in LEC GaAs. The hydrogen concentration is up to 50% of the carbon concentration in MOMBE GaAs and up to 20% in MOCVD GaAs. Fortunately, it can be removed by a post-growth heat treatment at 600°C for around 10 min.

23.5.3 LTMBE GaAs

The low growth temperature and an excess of As cause this material to be very As-rich [23.47, 88]. Initially the excess As is in solution and device processing causes it to precipitate. For reasons of reproducibility, an anneal at around 500°C is applied before processing which stabilises the LTMBE GaAs, which now contains a very high number of As precipitates and increases its resistivity to over $10^8 \Omega \text{ cm}$ [23.89]. The high resistivity is probably due to high concentrations of point defects, especially EL2, but Schottky barrier effects, resulting from the As/GaAs interfaces, which would result in virtually all the material being depleted, cannot be ruled out [23.90]. The acceptor species, which must be present to ionise the EL2 defects and pin the Fermi level, is widely believed to be the Ga vacancy, V_{Ga} [23.91] and there is some positron-annihilation spectroscopy evidence to support this [23.92].

23.6 Impurity and Defect Analysis of GaAs (Chemical)

Concentrations of impurities in all grades of GaAs, with the exceptions mentioned previously, are extremely low and always less than 1 part per million (ppm) or $\approx 4 \times 10^{16} \text{ cm}^{-3}$. Secondary-ion mass spectrometry (SIMS), or similar techniques like glow-discharge mass spectrometry (GDMS), are the chosen method for detecting most impurity elements, see [23.93]. In these methods, the surface is ablated and ionised. The secondary ions from the material under investigation are then passed through a mass spectrometer before detection. Sensitivities of better than 10^{14} cm^{-3} are quoted by most SIMS and GDMS laboratories. Unfortunately, important species like hydrogen, oxygen and carbon are not detected with adequate sensitivity by these techniques unless considerable care is taken to remove these impurities from the vacuum ambient of the mass spec-

trometer. This normally requires extra pumping often by cryogenic means (cooling a section of the instrument to near liquid-helium temperatures to freeze impurities and remove them from the vacuum), atypical extra components of most spectrometers. Because impurities and their concentrations tend to be specific to manufacturers and GaAs is being improved continuously, an example of a chemical analysis is not given.

At low concentrations, C, H, and O are difficult to measure in epitaxial GaAs because of the low volume of material that is available for analysis. In bulk GaAs, C, and H are best detected using infrared absorption by localised vibrational modes (LVM). This technique exploits the fact that light impurities in a solid have vibrational frequencies that do not couple well to the lattice modes (phonons); they vibrate at frequencies above

the maximum optical-phonon frequency (Reststrahlen) and lose this energy only slowly to the lattice. This gives them a long lifetime and a narrow bandwidth, resulting in sharp absorption bands which fall in the mid- to far-infrared part of the spectrum at 4–30 μm . Because vibrational frequencies and their absorption strengths depend on the atomic weights of the atoms and their isotopic abundances, respectively, LVM measurements can reveal the atom type unambiguously in many circumstances [23.72].

Measurement of these narrow absorption bands, often employing a Fourier-transform infrared (FTIR) spectrophotometer and low sample temperatures, pro-

Fig. 23.17 An LVM absorption spectrum of GaAs doped with Si at a concentration of around $5 \times 10^{18} \text{ cm}^{-3}$. Lines due to Si_{Ga} donors are present at 384, 379 and 373 cm^{-1} , corresponding to vibrations of ^{28}Si , ^{29}Si and ^{30}Si on Ga lattice sites, respectively. Lines from Si_{As} shallow acceptors, [$^{28}\text{Si}_{\text{Ga}} - ^{28}\text{Si}_{\text{As}}$] nearest-neighbour pairs and complexes labelled Si-X and Si-Y, seen only at high Si concentration, are also seen. (After [23.72])

vides sensitive information not only of concentrations but also of the atomic environments of the impurity atoms.

Unfortunately, absorption from free carriers is very strong in this spectral region and this must be reduced, usually by irradiation of the sample with high-energy electrons. At suitably low fluences, this produces deep levels that compensate the material, apparently without otherwise affecting the impurities. However, this makes the technique difficult for routine measurements. SI GaAs does not need this treatment making it the method of choice for the measurement of carbon concentration (Sect. 23.5).

A LVM absorption spectrum of GaAs containing a high concentration of Si is shown in Fig. 23.17.

The importance of oxygen in commercial GaAs has been questioned for many years. However, the maximum concentrations detected in bulk material are usually below the sensitivity limit for chemical techniques or LVM absorption. The only reports of sizeable concentrations of O in LEC GaAs were based on few, carefully prepared crystals [23.94].

Other methods of chemical analysis are either in disuse or out of the scope of this short section and will not be discussed here.

23.7 Impurity and Defect Analysis of GaAs (Electrical)

23.7.1 Introduction to Electrical Analysis of Defects in GaAs

One of the simplest ways of assessing a sample of GaAs is a measurement of carrier concentration and mobility. This is easily achieved in conducting material by Hall effect analysis. Applications of the Hall effect to GaAs have been discussed in detail by Look in [23.95]. This rather simple measurement can give considerable information about concentrations of shallow and deeper electronic levels. However, its sensitivity to the latter is rather limited. Also measurements in SI GaAs are

complicated by the difficulty in passing sufficient current through the material to achieve a measurable Hall voltage and the extremely high source impedance of the latter. Fortunately, there exist other highly sensitive electrical assessment techniques that can be used.

However, before these are introduced the importance of mapping needs to be emphasised. It is clearly important to reveal changes of electrical parameters across a wafer and changes that may occur from wafer to wafer. These measurements must be performed rapidly and preferably without contact to the GaAs wafer. Such measurements are often limited to resistivity and as-

sume that this parameter does not vary with depth. For conducting materials, microwave eddy-current loss measurements can be made very rapidly with a resolution of a few mm. These mappers have been available commercially for many years. For SI GaAs the absorption of microwave radiation is very small and another technique, time-domain charge measurement (TDCM), has been developed [23.96]. This method, which measures the dielectric relaxation time in order to give resistivity data, can have a spatial resolution of a few tens of μm [23.97].

Shallow-Level Defects

In p-type GaAs shallow acceptors have an appreciable ionisation energy and in nondegenerate material the resulting free holes can often be frozen out by cooling to temperatures close to 4.2 K. The Hall effect can be very useful here. An Arrhenius plot extracted from carrier concentration measurements taken as a function of temperature can reveal this activation energy and, therefore, the acceptor. The presence of more than one acceptor makes the analysis more difficult; if compensating donors are present they are not revealed directly but mobility data can indicate their concentration.

This method does not work with n-type material because the ionisation energies of shallow donors are very similar and, although total donors concentrations can be established, identification is impossible. Once again, it is assumed that no acceptors act as compensating defects.

However, a more complex technique, photothermal ionisation spectroscopy (PTIS) can identify donors [23.99]. This is based on the fact that the energy, ΔE , to excite the bound s electron to its first excited 2p state depends on the donor type. In PTIS, the sample, with Ohmic contacts, is cooled to temperatures near 10 K. Its conductivity is measured under illumination with light from a monochromator. When the photon energy is equal to ΔE , the 1s electron is excited to the 2p state. It is now ionised very rapidly by thermal excitation to the conduction band where it can be detected as a photocurrent. PTIS is very sensitive (less than 10^{14} cm^{-3} has been cited) but it fails for concentrations much higher than 10^{16} cm^{-3} because overlap of the electron wavefunctions causes broadening of the 1s–2p transitions. Extra information can be obtained by application of a magnetic field, stress or other perturbations to the crystal and these are discussed in [23.100].

Deep-Level Defects

Deep levels are produced by many impurities and intrinsic point defects. In many ways, these are more

insidious than shallow levels as their presence is often only detected when fabricated devices fail to perform adequately. Deep levels can result in unexpected noise, parameter drifting, electrical hysteresis, poor light output from optoelectronic devices, etc. These effects arise from carrier trapping and subsequent de-trapping at deep levels, and their role as recombination–generation (RG) centres. Detection and measurement depends on whether the GaAs is SI or conducting.

SI GaAs. Deep levels can trap carriers, produced optically by illumination with above-band-gap light, and then release them thermally. The released carriers, electrons or holes, can produce a current in an external circuit. The temperatures at which different traps release their carriers can be used to determine their ionisation energies. This is the basis of thermally stimulated current (TSC) spectroscopy, a technique that is especially useful for assessing high-resistivity materials such as SI GaAs. See [23.101] for discussions of this and other electrical assessment techniques. Two Ohmic contacts are placed on the sample. After optical filling of the traps at low temperature and at zero applied bias, the temperature is increased at a constant rate with the GaAs under bias and a sensitive current meter in series with the voltage supply. The current in the external circuit shows a series of peaks corresponding to trap emptying, the deeper traps requiring higher temperatures before they can con-

Fig. 23.18 TSC spectra recorded on a 350- μm -thick sample of SI GaAs. The traps have been filled by illumination with white light for 3 min at 80 K. The reverse bias is 25 V. (After [23.98])

tribute. This technique is sensitive (10^{13} cm^{-3}) and can be semiquantitative. It cannot, however, show whether a deep level is an electron or a hole trap, because the emptying of either will produce the same external current. A typical TSC spectrum from a sample of SI GaAs is shown in Fig. 23.18.

Conducting GaAs. Application of TSC to conducting semiconductors with Ohmic contacts is impracticable because of the high temperature-independent background current that would flow. However, the filling and emptying of traps is still a useful approach. If a rectifying junction can be formed, applying a forward bias can fill traps; the subsequent application of a reverse bias produces a depletion layer in which the traps can empty thermally. The emptying of each trap type produces a flow of charge that changes exponentially with time so that each current pulse is a sum of several exponentials with different time constants.

Although the current in an external circuit could be used to perform the subsequent measurement, it is easily shown that more information can be obtained from the change in depletion-layer capacitance because this can reveal whether electrons or holes are being de-trapped. If this capacitance change transient, also a sum of exponentials, is analysed by applying the *rate window* concept [23.103], the data can be presented as a spectrum of capacitance change in that window versus temperature. This is known as deep-level transient spectroscopy (DLTS) and a typical spectrum from a sample of GaAs is shown in Fig. 23.19.

DLTS is quantitative, giving defect concentrations, ionisation energies, capture cross sections and the identification of the type of trap (electron or hole). The labelling of the deep levels in Table 23.2 followed the early application of DLTS to GaAs.

DLTS equipment includes a sensitive and fast capacitance meter, usually furnished by Boonton, Inc., and a control box that applies the forward and reverse bias voltages as well as applying the rate window analyser to the output. The sample must be placed in a variable-temperature cryostat. As a rule, DLTS is controlled by computer. Often the fabrication of a p–n junction is inconvenient and a Schottky contact is used. Because minority carriers cannot be introduced into a semiconductor by this means, DLTS will only be sensitive to majority-carrier traps. If minority traps are to be investigated using the Schottky barrier method, minority

Fig. 23.19 Minority and majority traps introduced by high-energy electron irradiation of a sample of n-type GaAs after the fabrication of a p⁺–n diode. After [23.102]. For further details [23.101]

carriers must be introduced using a pulse of above-band-gap light instead of forward-bias, optical DLTS (ODLTS), Fig. 23.19. The uses of the many variations of DLTS have been discussed and assessed by several workers [23.91, 95, 101].

The sensitivity of DLTS depends on the carrier concentration, which, for standard operation, must exceed the total deep-level concentration by more than an order of magnitude. Within this restriction, the sensitivity is about two orders of magnitude less than the carrier concentration, i.e. for undoped LPE GaAs with a carrier concentration of 10^{16} cm^{-3} , DLTS will be able to measure defects down to the 10^{14} cm^{-3} range.

Although DLTS is widely used, it has a serious disadvantage: each trap produces a wide peak and several traps of similar emission properties cannot be distinguished. So-called Laplace-transform DLTS has been developed to overcome this [23.104]. A rate window is no longer used but the transient is analysed directly in terms of its exponential components by applying an inverse Laplace transform. However, this is demanding in terms of temperature control and the linearity of capacitance measurement. Older techniques such as photo-capacitance spectroscopy are beyond the scope of this section but are reviewed in the books mentioned above.

23.8 Impurity and Defect Analysis of GaAs (Optical)

23.8.1 Optical Analysis of Defects in GaAs

For obvious reasons, analytical techniques that do not require electrical contacts to be made to the sample, or are otherwise nondestructive, are attractive to device manufacturers. Many of these are optical in nature. The use and limitations of *LVM* absorption has been addressed in Sect. 23.6 and that for measuring EL2 concentrations was described in Sect. 23.1.3. Other infrared absorption techniques are of limited interest; we concentrate on light emission, or luminescence, methods.

Photoluminescence (PL)

Luminescence in semiconductors results from the radiative recombination of excess carriers. With the exception of direct recombination via free excitons, luminescence takes place via the mediation of defects [23.105, 106]. The energies of luminescence bands give information of the defects, the intensities are related (albeit in a rather indirect way) to concentrations and the total luminescence intensity is related to concentrations of parallel, nonradiative recombination paths. If the excess carriers are produced optically, often by illumination of the sample with a laser beam, the technique is photoluminescence. Excitation using a beam of high-energy electrons in a scanning electron microscope (*SEM*) results in cathodoluminescence (*CL*). Although the scanning ability of the *SEM* allows *CL* to map the luminescence of the material, *CL* is rarely applied to GaAs.

In either method, excess carriers are produced within the top few μm of the surface. However, this is not the only volume that is probed by the technique, as these carriers will diffuse about one diffusion length, L_D , before they recombine. L_D will be greater in material where the minority carrier lifetime is greater; in general, this will be associated with better, more luminescent material. It follows that there are restrictions on the spatial information that can be obtained, better resolution being obtained with material of lower L_D . Moreover, excess carriers that diffuse to the surface are lost to the measurement as they recombine there without emission of light. This process is quantified by a *surface recombination velocity*, which increases strongly as the temperature is raised. *PL* and *CL* are usually performed at low sample temperature because this reduces thermal broadening of the emission lines and reduces the diffusion of excess carriers to the sample surface. The emitted light is passed through a high-resolution spectrometer before detection by either a suitable photomultiplier tube or semicon-

ductor (usually Si or Ge) detector. A Ge detector must be cooled, although cooling of all detectors generally results in less noise.

Low-Temperature Luminescence from Point Defects

Low-temperature luminescence from shallow acceptors often dominates the spectra of SI GaAs, the energy of the lines being approximated by $E_G - E_A$, where E_A is the energy of the acceptor relative to the top of the valence band. Because E_A depends on the acceptor species, the presence of a particular acceptor can be determined. Similar luminescence from donors is less easy to differentiate as they have similar values of E_D (where E_D is the energy level relative to the bottom of the conduction band). Luminescence from intrinsic deep levels is weak because recombination is mostly nonradiative. However, that from EL2 centres can be resolved both at low and at room temperature [23.98, 107]. The situation from impurity levels, especially transition metals, usually resulting from contamination is different with strong luminescence resulting from many. Of interest is the line due to Cu at 1.05 eV, which is particularly strong and well resolved and allows this common contaminant to be detected. The *PL* spectra from GaAs depend very sensitively on the method of growth, subsequent treatments and the presence of impurities. Readers interested in this technique are directed towards the relevant chapters of [23.1].

Room-Temperature Luminescence Measurements

The broadening effects of temperature and the increased influence of the surface greatly reduces the use of room-temperature luminescence as an analytical tool. However, mapping at room temperature is often attractive because of its relative ease compared to low-temperature studies. It is then a truly nondestructive method giving spatial information of surface properties (that control the surface recombination velocity) and it is often used for assessing substrates and the uniformity and quality of quantum wells (*QW*). A review of these techniques has been given by [23.108].

Mapping of Surface Properties. The surface quality of GaAs substrates is critical to successful epi-growth. Manufacturers perform special cleaning and oxidation procedures to ensure reproducible surface properties, those being suitable for immediate epi-growth being supplied as *epitaxial-ready*. A valuable check on these

properties is scanning PL as changes to the surface result in changes to the surface recombination velocity. Of course, this assumes that the material is well annealed and that residual nonuniformities in point-defect concentrations do not otherwise affect the recombination kinetics, a situation that is never fully achieved. There is no need for a spectrometer in this measurement as the total PL efficiency is altered by the surface and, in any case, PL line widths are thermally broadened. Collection of all the luminescence means that a relatively high signal is detected, with a concomitant increase in the measurement rate. Small-scale structures are often associated with residual volume nonuniformities (see, for example, [23.109]) whilst large-scale effects are most often due to polishing and subsequent contamination of the surface [23.110].

23.9 Assessment of Complex Heterostructures

Most electrically active GaAs, as opposed to substrate material, is used in complex device structures consisting of several layers. In many optical and microwave devices these layers will be of GaAs and $\text{Ga}_{1-x}\text{Al}_x\text{As}$, where x may take several values and the carrier concentration and thickness of each layer is critical.

23.9.1 Carrier Concentration Measurements in Heterostructures

Although Hall-effect measurements accompanied by a process where the surface is gradually removed by chemical dissolution can be used to assess material of more than a single layer, more complex structures normally use capacitance–voltage (CV) profiling. This method is sensitive and has good thickness resolution. However, it does not give carrier mobility information. Some point-defect information can be derived from the frequency dependence of the data, although expert analysis is required. CV measurements are normally a part of DLTS instrumentation and suitable software is then available to analyse the data see [23.93, 101]. In some situations, where individual layer thicknesses exceed a micron or so, the wafer can be cleaved (normally to reveal a {110} surface) and etched in a solution that stains the layers according to doping type and material. Such a cleaved and stained surface can be viewed in an optical microscope and probed electrically for rapid assessment [23.93].

Mapping of Quantum-Well Properties. Quantum wells act as very efficient collectors of excess carriers and are, in general, highly efficient radiative centers. This is the reason for their use in lasers, LEDs, etc. The reproducibility of QW characteristics, especially in terms of QW widths and the quality of the barriers, across large substrates and from wafer to wafer is a key to successful device manufacture and a challenge to all epitaxial growth techniques. Two-dimensional mapping of room-temperature PL using a spectrometer to resolve the spectrum is used to assess the uniformity of these properties. Although the time to map a wafer depends on the spatial and spectral resolution that is required, the efficient radiative recombination at QWs and the bright luminescence makes this a relatively rapid process [23.111].

Fig. 23.20 H, O, Si, S, and As depth profiles in reactive-ion-beam sputtered Si_3N_4 film on GaAs as determined by SIMS. (After [23.112])

Fig. 23.21a,b Experimental and theoretical rocking curves from a 165-Å-thick layer of $\text{In}_{0.18}\text{Ga}_{0.82}\text{As}$ on GaAs, (a) at the wafer centre and (b) near the wafer periphery. The vertical scales are logarithmic. Note the complexity of these curves for this relatively simple system

23.9.2 Layer Thickness and Composition Measurements

Layer thickness and composition are normally measured together. As an example, dynamic SIMS, where the atomic composition and layer thickness is measured as the ablation of the surface takes place, gives this information effectively, at least for the first few microns of depth. At greater depths, the flatness of the floor of the ablated material degrades. Except that SIMS is destructive, it is often the method of choice [23.93]. Spatial mapping is possible in principle but the increase in machine time makes this prohibitively expensive as a routine procedure. A SIMS profile of a Si_3N_4 film on GaAs, demonstrating the depth resolution and large sensitivity range, is shown in Fig. 23.20.

A nondestructive approach is that of X-ray diffraction, normally double-crystal X-ray diffraction (DXD). X-rays are emitted from a tube and then conditioned by diffraction from a first crystal of high-structural-quality GaAs. The radiation is then diffracted by the sample, which can be tilted to move it in and out of the diffraction condition. A scintillation counter or semiconductor detector detects the diffracted X-rays.

Only the symmetrically diffracted beam is normally used for routine assessment, although other diffraction spots can be more sensitive to the surface structure as the penetration of the beam can be less in these cases. The diffracted energy as a function of tilt is presented as a *rocking curve*, which reveals the small dispersion of the total diffracted energy resulting from lattice strain and other effects. Penetration of the X-rays into the top few microns of a complex structure results in a more complicated rocking curve. However, in virtually all cases, most of this diffracted energy comes from the substrate and diffraction from the epilayers results in small additions to the wings of the rocking curve. It follows that the curve has a large dynamic range of several orders of magnitude and that it can take many hours to obtain the entire curve. Analysis of the rocking curve requires

considerable computation so that the entire process is time-consuming. Often the rocking curve is compared to a computer simulation so that the calculation has to be performed only once. For reviews of these techniques, see [23.113, 114].

Spatial mapping of the rocking curves from substrates to map changes in lattice constant and residual strain is possible, as the rocking curves are simple. However, mapping from complex structures is extremely time-consuming. Figure 23.21 shows rocking curves from a 165-Å-thick layer of $\text{In}_{0.18}\text{Ga}_{0.82}\text{As}$ on GaAs, (a) at the wafer centre and (b) near the wafer periphery. The lower curve of each set of data is a theoretical fit to the experimental curve above.

23.10 Electrical Contacts to GaAs

It is clearly necessary to make electrical contacts to a GaAs device. These are of two types, those with a small internal barrier voltage and which do not affect the passage of a current, *Ohmic* contacts, and those whose internal electrical fields result in a sizeable potential difference and which modify the current flow, non-Ohmic or Schottky contacts.

23.10.1 Ohmic Contacts

A true Ohmic contact would exploit the constancy of the Fermi energies in the semiconductor and the metal. Such a situation rarely occurs and the true nature of practical Ohmic contacts often remains unclear. As an example, the most commonly used Ohmic contact to n-type GaAs is the eutectic alloy of Au–12% Ge. This is evaporated onto the surface and then heated to about 400 °C to produce the required electrical properties. It is believed that the heat treatment results in the in-diffusion of Ge to produce an extremely thin n^+ region, although this may not be the only mechanism; electron microscopy shows that complex intermetallic reactions between the Au–As and Ge take place. If Ni is added to the Au–Ge alloy to produce a ternary, a greatly improved contact results, certainly as a result of the Ni reacting with the GaAs surface to produce intermetallic phases with As and possibly by removing the oxide layer. Other contact materials are sometimes used and many of these have been reviewed in [23.95].

Ohmic contacts to p-type GaAs often use evaporated Au–Zn alloys followed by a heat treatment similar to that used for n-type contacts. The in-diffusion of Zn atoms clearly takes place but the removal of oxides on the GaAs surface by the Zn is also important.

23.10.2 Schottky Contacts

The barrier height between most metals and n-type GaAs is found to be nearly constant at 0.6–0.7 V. This high and constant value is a result of the Fermi energy at the surface being controlled by surface electronic states rather than the properties of the metal. Titanium is the most important Schottky contact. It is usually introduced via a TiPtAu alloy. This exploits the high sticking coefficient of Ti to GaAs whilst the Pt acts as a diffusion barrier to the low-electrical-resistance Au metallisation that would otherwise enter the GaAs. TiAl is sometimes a preferred alternative.

Interestingly, Al also produces a Schottky barrier on p-type GaAs with a barrier height of about 0.6 V. Gold was used as a Schottky contact on n-type GaAs with a barrier height of about 0.9 V but, as discussed above, this is degraded by in-diffusion at high temperatures. Contacts used specifically for high-temperature use include some silicides, with WSi_x being commonly used in some microwave devices. Metals for Schottky contacts have been reviewed in [23.115].

23.11 Devices Based on GaAs (Microwave)

23.11.1 The Gunn Diode

The occurrence of secondary conduction-band minima in the E – k diagram of GaAs leads to the possibility of high-energy electrons being excited from the Γ point where they have low effective mass to the X points where their mass is much greater. This is the transferred-electron effect. Although on applying a greater electric field their kinetic energy is increased, their increased mass leads to a fall in velocity. As a result, the current falls. This appears as a negative differential resistance (NDR) region in the current–voltage characteristics [23.116–118]. If an applied bias keeps the current flow in the NDR region, it can be shown that the electron flow will break up into pulses and the cur-

rent in the external circuit will also be pulsed. Under certain circumstances, this results in the production of power at a particular microwave frequency determined mainly by the thickness of the GaAs [23.119]. The device optimised for microwave power production is called the *Gunn diode*, after J. B. Gunn who first observed this effect experimentally. This device is shown in Fig. 23.22.

The device is very simple, consisting solely of a few microns thickness of high-purity n-type ($\approx 10^{15} \text{ cm}^{-3}$) GaAs with more highly doped contacting regions to improve connection to the outside world [23.120]. The Gunn diode can produce microwave emission at frequencies up to 10 GHz and with powers of a few Watts. These devices have uses as portable microwave sources in radar speed detectors, for example.

23.11.2 The Metal–Semiconductor Field-Effect Transistor (MESFET)

As discussed in the introduction, the increased mobility of electrons in GaAs over those in Si seem to offer the prospect of faster devices, especially improved microwave transistors. This turns out to be based on an oversimplistic interpretation as to how these devices really work. However, consider the first, three-terminal GaAs microwave device, the metal–semiconductor field-effect transistor (MESFET) whose structure is presented in Fig. 23.23.

The MESFET is similar to the Junction Field Effect (JFET) in Si technology with the p–n junction gate being replaced by a simple Schottky gate. Ti-based alloys are normally used for the Schottky contact as these adhere well to the surface. Application of a voltage to the gate modulates the width of the conducting channel and hence its conductivity. The channel is connected to two

Fig. 23.22 The Gunn diode. The active region is the low-doped n-type GaAs in the centre. (After [23.120])

Fig. 23.23 The MESFET. Current flows only in the undepleted region. L is the gate length and determines the speed of the device; z is the gate width and controls the maximum current capabilities of the device; h is the channel thickness. (After [23.121])

highly doped contact regions where ohmic contacts are made. These are the source and drain.

Initially all MESFETs were made by donor ion implantation into SI GaAs substrates using the methods described in Sect. 23.4. However, more recent methods including epitaxial growth by MOCVD and MBE result in higher effective doping levels, more abrupt interfaces, especially at the rear of the channel where a rapid change in carrier concentration is critical and the possibility of depositing alloys such as GaAlAs. Ion implantation is still used throughout the industry, however, especially for digital circuits.

In operation, the gate bias causes the channel to be pinched off. The drain–source voltage produces an extremely high field near the pinched-off channel and the channel current is saturated. Figure 23.24 shows that under these circumstances the electron velocity is expected to be saturated at $\approx 5 \times 10^6$ cm/s, a result of velocity saturation and the transferred-electron effect, the latter producing the reduction in velocity at higher fields.

This value is actually *less* than the saturated electron velocity in Si at similar electric fields and it is clear that the advantages of low electron effective mass at low fields in GaAs are not important. However, microwave measurements show an unexpected extension of high-frequency amplification especially with MESFETs with a small gate length. This is caused by the extremely short

Fig. 23.24 Drift velocity of electrons and holes in Si and GaAs. At low electric fields the carrier velocities increase linearly with electric field (Ohm's law). However, at high fields saturation takes place. The reduction in velocity of electrons in n-type GaAs is a result of the transferred-electron effect. (After [23.4])

Fig. 23.25 The GaAs/AlGaAs HEMT. (After [23.125])

time that electrons are in the channel, which does not allow them to lose their kinetic energy to the lattice. This effect, known as *velocity overshoot*, allows electrons to reach a velocity near 2.5×10^7 cm/s in short-channel devices and is the first true reason for the high-frequency capability of the GaAs MESFET; the other is the use of a SI substrate. The latter reduces the parasitic capacitances that exist between the device and its contact pads and ground. The cut-off frequency of GaAs MESFETs is inversely proportional to the gate length and is 110 GHz for a gate length of 0.15 μm . The MESFET is discussed in detail in [23.122–124].

23.11.3 The High-Electron-Mobility Transistor (HEMT) or Modulation Doped FET (MODFET)

The channel of a GaAs MESFET must be doped with donor atoms to produce the necessary free carriers. Scattering by the positively charged donor ions results in a reduction in electron mobility and increased noise. In the HEMT the free carriers in the channel are produced by diffusion of electrons from an n-type layer of greater band-gap energy such as GaAlAs.

GaAs buffer layer	0.5 μm	Undoped
Semi-insulating GaAs substrate		

Fig. 23.26 The layer structure of the AlGaAs/InGaAs pHEMT. (After [23.125])

A diagram of a GaAs/GaAlAs HEMT is shown in Fig. 23.25.

The GaAlAs supply layer of 50 nm thickness, doped n-type to a concentration of about $2 \times 10^{18} \text{ cm}^{-3}$, supplies the free electrons. Alternatively, this layer can be delta-doped with a suitable donor. The undoped GaAlAs layer of about 2 nm thickness reduces Coulombic effects between the donors in the GaAlAs and the electrons in the channel which would otherwise reduce their mobility. The thickness of the undoped GaAs channel layer is not critical and is typically less than 1 μm . Advantages of this HEMT structure are best revealed at low temperature where effects due to phonon scattering are also minimised. However, even at 300 K this device is faster and less noisy than a comparable MESFET. This is because the real improvement in performance comes from the heterojunctions which act to constrain the carriers close to the gate with a resultant increase in high-frequency performance.

One disadvantage of the simple HEMT is the poor transfer of electrons from the GaAlAs to the GaAs channel resulting from the rather small conduction-band discontinuity at the interface. This results in a relatively low electron concentration in the channel and a large residual electron concentration in the supply layer, which acts as a slow GaAlAs MESFET in parallel with the HEMT. For this and other reasons, the simple GaAs/AlGaAs HEMT has been replaced by the pseudomorphic HEMT (pHEMT).

The pHEMT exploits the greater conduction-band discontinuity that exists between GaAlAs and InGaAs. Although there is a large lattice mismatch between GaAlAs and InGaAs, the latter can be grown as a thin, (12-nm) pseudomorphic layer on GaAs. The resulting structure is shown in Fig. 23.26.

Cut-off frequencies up to 300 GHz have been reported for these devices, which can also be designed for use as power devices. There is a strong commercial market for MMICs employing pHEMTs in many microwave applications. These include mobile phones, domestic satellite TV antennas and radar and space use. Again, [23.122–124] offer an excellent description of these device types.

23.11.4 The Heterojunction Bipolar Transistor (HBT)

The current gain of a bipolar homojunction transistor is optimised by having an emitter doping that is much higher than the base doping and a base width

Fig. 23.27 Schematic diagram of a heterojunction GaAs/AlGaAs bipolar transistor. The collector contact is made to the rear of the device. (After [23.121])

that is as small as possible [23.121]. Unfortunately, high-frequency operation requires a high doping level in the base to reduce the base resistance. This must be accompanied, therefore, by very heavy emitter doping. However, such heavy doping leads to band-gap shrinkage, resulting in high base injection current and a reduction of the current gain. This argument is true both for npn and pnp homojunction bipolar transistors.

An elegant solution to this problem uses different materials in the device; for an npn device, a heavily doped, n-type, wide-band-gap emitter, a heavily doped p-type base and a lightly doped, n-type wide-band-gap collector. This is the **HBT**.

The base–emitter heterojunction offers a different barrier to hole injection from the base and electron injection from the emitter, resulting in efficient minority-carrier injection into the base [23.126, 127]. The base–collector junction need not be of different materials but a heterojunction may increase the breakdown voltage at the collector. The GaAs/GaAlAs system can be used for these devices, as shown in Fig. 23.27, although **HBTs** based on the alternative GaAs/GaInP

system are superior and have a large market in applications like mobile phones.

Typically, **HBTs** have f_t values of around 40 GHz, although devices with $f_t > 160$ GHz have been reported. They can produce more power per unit area of device than a **MESFET** or **MODFET**. However, catastrophic breakdown can occur at the collector–base junction. High-temperature operation can result in rapid ageing effects, resulting from diffusion of acceptors from the base into the acceptor region. Because of its low diffusion coefficient the use of carbon as the acceptor in the base has reduced these problems. Readers are referred to [23.122, 124] for further reading. **HBTs** find extensive use in mobile telephony, where they are efficient microwave power sources.

23.12 Devices based on GaAs (Electro-optical)

The range of GaAs based electro-optical devices can be separated into emitters, modulators and detectors, the former being of much greater commercial interest than the others.

23.12.1 GaAs Emitters

Light-Emitting Diodes

The direct band gap of GaAs has made it popular for the fabrication of **LEDs** for several decades. The simplest **LED** is a p–n junction in GaAs, which in the early days, was fabricated by diffusing Zn into n-type material. The internal efficiency of this early device was poor at only a few percent but improvements in both material and processing showed that it could be surprisingly high, near 100%, even in such a simple structure. However, the external efficiency is always poor, with most of the emitted radiation being reflected back into the GaAs where eventually it is reabsorbed. This is because of the high

refractive index of GaAs ($n \approx 3.5$), which, for a planar p–n junction, gives a maximum external efficiency from a single face of 2%. There are several approaches to extracting more light from the **LED** and these have been discussed by *Schubert* [23.128]. The use of lenses, antireflection coatings and epoxy domes are only three of the many commercial practices that improve the external efficiency of a simple GaAs p–n junction.

GaAs can be used as a basis for **LEDs** that cover the wavelength range from green (560 nm) through to **IR** wavelengths of over 1000 nm. Table 23.3 is a list of commercial **LEDs** based on GaAs.

The first entry $[(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}]$ is a series of quaternary alloys, all of which have direct band gaps, and lattice-match to GaAs for any value of x . This gives a wide range of colours in the visible part of the optical spectrum. These alloys are grown by **MOCVD** and, although much more expensive than **LEDs** based on simpler materials, have the advantage of being very

Table 23.3 Light-emitting-diode materials and their properties. (After [23.125])

Active region	Gap	Substrate	Lattice match	Wavelength (nm)	Color
$(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$	D	GaAs	Yes	560–640	Green, yellow, orange, red
$[\text{Al}_x\text{Ga}_{1-x}\text{As}-\text{GaAs}]$ MQW ($x < 0.45$)	D	GaAs	Yes	630–870	Red to IR
$\text{Al}_x\text{Ga}_{1-x}\text{As}$ ($x < 0.45$)	D	GaAs	Yes	630–870	Red to IR

$\text{Ga}_{1-x}\text{In}_x\text{As}$	D	GaAs	Yes	> 870	IR

MQW–Multiple quantum well; SL–superlattice; D–direct gap in k space; I-RS–indirect in real space; IR–infrared

bright and efficient. Light emission from the rear of the device is not possible because the GaAs substrate absorbs it. If a thick layer of GaP is grown as the top layer, a variation of this device can be fabricated where the entire GaAs substrate is removed by etching and the GaP becomes a new substrate. Because the

$(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$ is now the material with the lowest band-gap energy, all the light is available for emission from the device and the external efficiency is markedly improved.

The second entry represents multiple quantum wells (MQW) based on GaAs wells with GaAlAs walls and whose confined electron states depend on the well widths. The recombination of excess carriers in the wells efficiently produces light emission, the wavelength of which is engineered by modifying the well widths. These LEDs can emit red light efficiently.

The third entry is for bulk $\text{Al}_x\text{Ga}_{1-x}\text{As}$ where the emitted light wavelength depends on the value of x . In both this and the previous case, x must be less than 45% because at higher fractions of Al the band gap becomes indirect and the efficiency for optical emission falls rapidly. Both these structures allow emission from 630–870 nm to be achieved.

The fourth entry has been mentioned in relation to grading in epitaxial growth. $\text{GaAs}_{1-x}\text{P}_x$ alloys have been the basis for low-cost visible LEDs for many years, those suitable for growing on n-type GaAs, resulting in red emission. Green- and yellow-emitting LEDs are based on GaP substrates. Grading the alloy composition from n-type GaAs until the required n-type $\text{GaAs}_{1-x}\text{P}_x$ alloy is grown produces the correct composition for emission. The next growth is of p-type material of the same composition to produce the p–n junction. The p-type contact is made to the top of this structure to complete the LED.

The next entry relates to the simple GaAs LED while the next demonstrates the use of heavy Zn doping which leads to band-gap narrowing and the emission of light

Fig. 23.28 The structure of a GaAs-based RCLED. The active region is a multiple-quantum-well structure. The lower reflector is a distributed Bragg reflector formed by growing a series of AlAs and GaAs layers so that each has an optical thickness of $\lambda/4$ giving near 100% reflectivity at the chosen wavelength. The upper reflector is the simple SiO_2 interface. (After [23.129])

of wavelengths longer than 870 nm. A similar effect has been found by using doping superlattices.

The final entry is an attempt to lower the band-gap energy of GaAs by the addition of In to make $\text{Ga}_{1-x}\text{In}_x\text{As}$ alloys. These alloys are not lattice-matched to GaAs and the introduction of misfit dislocations at the growth interface results in nonradiative processes and a reduction in the efficiency.

Simple IR GaAs LEDs are mass-produced for use in infrared remote controls, optoisolators, emitters for low-cost fibre-optic networks, etc. High-efficiency visible LEDs have a very large market in portable and permanent displays. The former uses include mobile telephones and laptop computers. The second includes advertising and other public displays.

Highly efficient LED structures include the resonant-cavity LED (RCLED) where the emission takes place in a cavity tuned to the emission wavelength. The spontaneous emission along the axis of the resonant cavity is strongly enhanced and the increase in light output in this direction can be more than 10 times that of a more conventional LED. The structure of a RCLED is shown in Fig. 23.28. It should be compared to that of a vertical-cavity surface-emitting laser in the next section.

The recent work dedicated to light-emitting diodes by Schubert is recommended for further reading [23.128].

Lasers

The major difference between an LED and a laser is the existence of a resonant cavity and the confinement of the light in the cavity, which encourages stimulated rather than spontaneous emission in the laser. The use of GaAlAs is very important for the optical confinement as its lower refractive index produces total internal reflection along the axis of the laser. The optical cavity is often produced by simply cleaving parallel {110} facets on the ends of the cavity, the laser being fabricated on a {001} substrate. The high current density that is required to ensure population inversion in the laser is accomplished by careful engineering of the contact metallisation.

There are several types of GaAs laser structure but these can be separated into those where the lasing takes place in bulk material and those where this region is modified by using quantum wells.

Laser-diode structures have been reviewed in [23.130–132] and in many other general textbooks on semiconductors.

The GaAs/AlGaAs Heterojunction Laser. This type of laser is typical of those used in compact disc players,

etc. The structure and operating conditions are shown in Fig. 23.29a and b.

Stimulated emission takes place in the GaAs active region, where excess carriers are injected from the surrounding p- and n-type regions. Different lasers have either GaAs or GaAlAs as these adjacent layers. We dis-

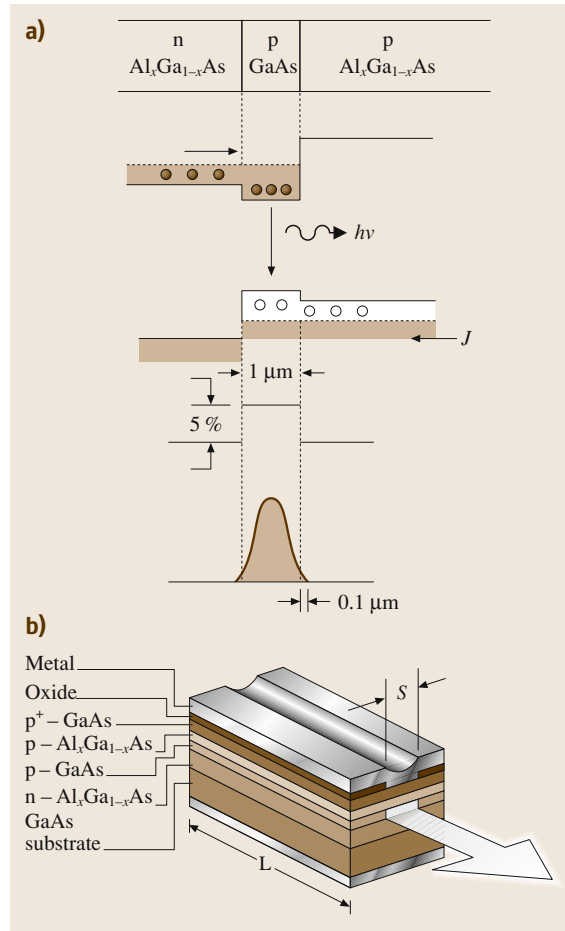

Fig. 23.29 (a) Band-gap diagram of a simple double heterojunction, GaAs/AlGaAs laser. The injected carriers are effectively trapped in the GaAs active region where they recombine to produce light. The increase of refractive index in the active region also constrains the light by total internal reflection. Thus both electrical and optical confinement is achieved. (b) Final structure of a GaAs/AlGaAs ridge laser. The n^+-GaAs substrate and upper p^+-GaAs layers are used for the contacts as metallisation to AlGaAs is less satisfactory. The SiO_2 oxide layer provides further electrical confinement. The optical cavity is defined by the {110} end facets. (After [23.4])

cuss only those lasers with GaAlAs on either side of the active layer, the double heterojunction (DH) laser, as these are most commonly used.

Electrons and holes introduced from the adjacent GaAlAs layers are effectively confined to the GaAs active layer because of the conduction- and valence-band offsets that exist at the heterojunctions. However, this is not optimal for optical confinement and further cladding by $\text{Ga}_{0.4}\text{Al}_{0.6}\text{As}$ is often necessary. This modification results in the device known as the separate confinement heterojunction (SCH) laser. However it is achieved, GaAlAs cladding layers must always surround the active layer to produce optical confinement.

In some designs, the Al content of the GaAlAs cladding layers is graded with the Al content increasing linearly with the distance from the active layer. This graded refractive index (GRIN) structure has optical and electrical advantages and obviates the use of two separate confinement layers. The final structure is often called a GRINSCH laser. A layer of insulating SiO_2 with a thin axial opening to allow electrical connection to the upper p-type layer achieves the electrical confinement. Emission occurs at around 800 nm if GaAs is used in the active layer. If it is replaced by GaAlAs with a low Al content, the emission wavelength can be reduced. Laser structures were originally grown by LPE but large-scale production uses MOCVD or even MBE, although GRINSCH lasers are usually grown by MOCVD. There is a rather high dependence of emission wavelength on temperature with these simple lasers. The use of distributed optical feedback stabilises the output. Though outside the confines of this review, details of these lasers can be found in [23.134].

Although many millions of small GaAs/GaAlAs lasers (less than 20 mW output) are sold annually for domestic applications such as CD players, these lasers can be designed to produce powers exceeding 50 W and are used for pumping Er-doped quartz amplifier fibres for communications use. High-power lasers are not as rugged as smaller units and can suffer from catastrophic failure at the reflecting facets. Special treatments have to be used to prevent these failures.

The Red-Emitting, GaAs/GaAlAs Multi-Quantum-Well (MQW) Laser. The efficient radiative recombination that can occur in quantum wells has been exploited in the design of red lasers based on the GaAs/GaAlAs system. Attempts to produce a red-emitting laser using a conventional active layer fail because GaAlAs with the necessary Al content has an indirect band gap and, therefore, low emission efficiency. However, replacing

Fig. 23.30 The band structure of a GRINSCH single-QW laser. The large-band-gap material is $\text{Al}_{0.6}\text{Ga}_{0.4}\text{As}$. This is graded to $\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$ towards the centre of the device, providing electrical and optical confinement. The active region is the $\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}/\text{GaAs}/\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$ quantum well at the centre. The emission wavelength depends on the width of this well, which is typically 1–4 nm. In a GRINSCH MQW laser there is a series of several identical quantum wells. Barriers of typically 5 nm thickness separate them. (After [23.133])

this layer with a series of quantum wells increases the energies of the trapped electrons and holes with respect

Fig. 23.31 The vertical cavity surface emitting laser (VCSEL). The optical cavity is vertical being defined by the two dielectric mirrors (Distributed Bragg Reflectors). The active region is a multi-quantum well structure at the centre of the device

to the conduction band and the valence band, respectively [23.133]. This effect is the same as used in the **MQW LED**. The structure of a red-emitting **GRIN SCH QW** laser is shown in Fig. 23.30.

These lasers are used in digital versatile disc (**DVD**) players, visible pointing devices, light pens, and several other devices where a visible narrow light beam is important, and where a larger and more expensive He/Ne would have been used previously. The mass production of this complex structure has resulted in the price of these lasers being reduced to the single-dollar range. The **MQW**s in these lasers are very narrow, involving layers that are only a few lattice spacings wide. This is the regime where pseudomorphic growth is possible. Thus, the use of GaAs/GaInAs **MQW**s within GaAlAs cladding layers has produced lasers emitting in the range 0.85–1.0 μm .

The Vertical-Cavity Surface-Emitting Laser (VCSEL). The standard heterojunction laser suffers from several disadvantages from a fibre-optic systems point of view. It is difficult to coat the exit facets with antireflection coatings, it is very difficult to integrate this type of device with microwave amplifiers such as **MESFET**s and the output beam has a cylindrical cross section that is not optimised for injection into a fibre. The **VCSEL** attempts to overcome these problems (Fig. 23.31).

The light is amplified by a **QW** active region as only the **QW** has sufficient gain over such

a thin layer to allow lasing. Even then, the use of simple cleaved mirrors would reduce the overall gain below that necessary for laser operation. Highly reflective multilayer dielectric reflectors (distributed Bragg reflectors often made from a series of GaAs/AlGaAs layers below and above the active layer) are necessary. However, the final device is truly planar, providing a beam of circular cross section. Output powers of several mW have been obtained [23.136] together with integration within a **MESFET** integrated circuit [23.137]. Advanced semiconductor diode lasers and their incorporation within integrated circuits are thoroughly described in [23.137, 138].

23.12.2 GaAs Modulators

It is sometimes necessary to modulate the intensity of a light signal electrically after it has been produced. The near-band-edge absorption of quantum wells can be moved to longer wavelengths by the application of a reverse bias. This is the quantum-confined Stark effect [23.139] and this is the basis of the **MQW** modulator. The modulator structure and the change of near-band-edge absorption with applied voltage are shown in Fig. 23.32.

This device can operate at frequencies up to 40 GHz and has spawned a series of more-advanced devices that are discussed in [23.135].

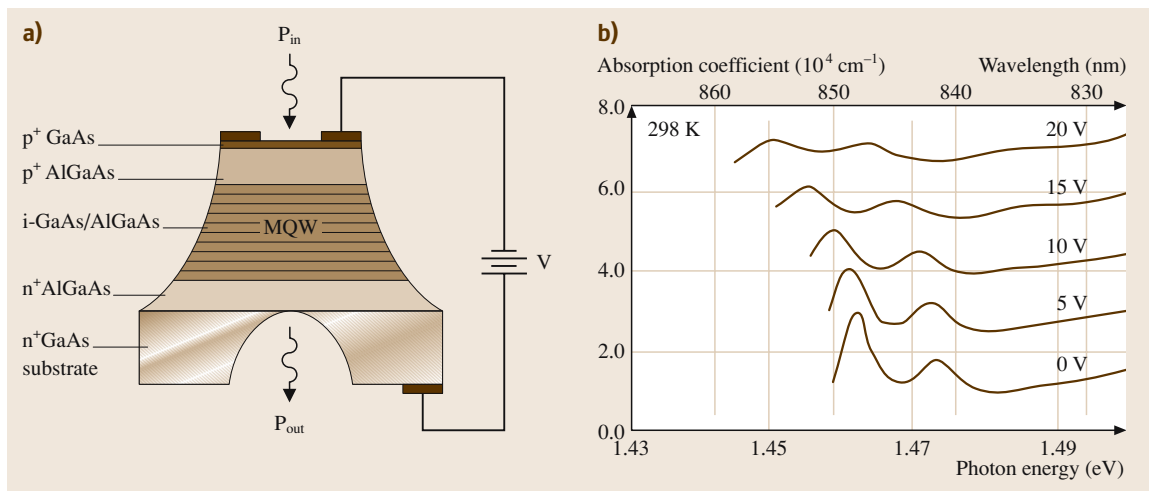

Fig. 23.32a,b The **MQW** optical modulator uses the changes in the near-band-edge absorption spectrum that occurs on the application of an electric field. The device is shown in (a) where it can be noted that the layer structure is very similar to a **MQW LED**. It is, however, operated under reverse bias. (b) Changes in absorption that occur in a **MQW** when a bias is applied. (After [23.135])

23.12.3 GaAs Photodetectors

Solar Cells

As a bulk material GaAs has found great use in solar cells. There are many reasons for this.

1. The band-gap energy is well matched to the solar spectrum and the high optical absorption above the band edge means that most light is absorbed in a thin layer.
2. In extraterrestrial applications, where large numbers of high-energy atomic particles exist, GaAs solar panels damage less easily than Si panels and therefore retain efficiency for longer.
3. In terrestrial use the higher band-gap energy allows GaAs solar cells to operate in concentrator systems (at the focus of a large Fresnel lens which is mechanically aimed at the Sun) where high temperatures are inevitable and Si devices would lose efficiency.

The simplest structure of this device is a simple p-n junction of high-quality GaAs. It is normally covered with a GaAlAs top layer to passivate the surface and to reduce reflection losses. These devices can have an efficiency of over 20% [23.140] Structures that are more

complex involve up to three solar cells grown in series. In a typical two-cell structure, the light sequentially passes through a GaAs solar cell and then a similar GaSb device. Much of the sub-band-gap light that is transmitted by the GaAs is absorbed in the GaSb solar cell ($E_G = 0.72$ eV). Because these solar cells are effectively in series with reducing band-gap energies, more of the sunlight is absorbed than if a single cell were used. The efficiency of these devices can reach 30%. Research and development of multi-junction structures, often using Ge as a substrate and with different layers including GaAs, is very active. Because of their size, especially for space application, solar cells represent a sizeable part of the overall market for GaAs.

Other Photodetectors

The large band-gap energy makes GaAs unsuitable for most optical detector applications; the light generated by GaAs emitters being detected by Si or low-band-gap ternary detectors. However, the ionisation of electrons from bound QW states into continuum states can result in tunable mid- and far-IR detectors. The GaAs/GaAlAs system has been used in this way to make imaging arrays for wavelengths up to $20\mu\text{m}$, see for example [23.141].

23.13 Other Uses for GaAs

There have been attempts to exploit GaAs in other fields. High-energy particle detectors, including those for imaging X-rays, measure the ionisation produced as the particle traverses the detector material. The high stopping power, the large band-gap energy, which reduces leakage current, and the increased radiation hardness of GaAs in comparison with Si would appear to make it suitable for detectors for both scientific and medical use. The ready availability of SI GaAs wafers

has encouraged this work. Unfortunately, these detectors suffer from effects resulting from the presence of deep levels, especially EL2 [23.142]. One application that has shown promise is in high-temperature sensors, amplifiers and processors in automotive, aeronautical and other uses. This exploits the high band-gap energy of GaAs, which allows devices to work at temperatures up to 300°C . An excellent review has been given in [23.143].

23.14 Conclusions

GaAs technology is now mature with devices occupying important niches in the semiconductor marketplace. I have presented the fundamental properties of GaAs and have demonstrated how its unique set of characteristics has allowed it to be exploited in several microwave

and optoelectronic applications. Future developments will probably concentrate on further integration of known devices and improvements to speed, power and reliability rather than the development of novel ones.

24. High-Temperature Electronic Materials: Silicon Carbide and Diamond

The physical and chemical properties of wide-band-gap semiconductors make these materials an ideal choice for device fabrication for applications in many different areas, e.g. light emitters, high-temperature and high-power electronics, high-power microwave devices, micro-electromechanical system (MEM) technology, and substrates for semiconductor preparation. These semiconductors have been recognized for several decades as being suitable for these applications, but until recently the low material quality has not allowed the fabrication of high-quality devices. In this chapter, we review the wide-band-gap semiconductors, silicon carbide and diamond.

Silicon carbide electronics is advancing from the research stage to commercial production. The commercial availability of single-crystal SiC substrates during the early 1990s gave rise to intense activity in the development of silicon carbide devices. The commercialization started with the release of blue light-emitting diode (LED). The recent release of high-power Schottky diodes

was a further demonstration of the progress made towards defect-free SiC substrates.

Diamond has superior physical and chemical properties. Silicon-carbide- and diamond-based electronics are at different stages of development. The preparation of high-quality single-crystal substrates of wafer size has allowed recent significant progress in the fabrication of several types of devices, and the development has reached many important milestones. However, high-temperature studies are still scarce, and diamond-based electronics is still in its infancy.

The electronic revolution of the 20th century is mainly based on silicon, which can be regarded as the first-generation semiconductor. Around the turn of the 21st century gallium arsenide and indium phosphide have evolved as second-generation semiconductors, constituting the base for the wireless and information revolution. Now at the start of the 21st century, the wide-band-gap semiconductors silicon carbide and gallium nitride are on the rise and may be regarded as third-generation semiconductors used in the electronic and optoelectronic industries. Moreover given diamond's superior properties and the recent surge of research on diamond preparation and fabrication of diamond-based electronic devices, one might speculate that diamond may be a future-generation semiconductor.

The effects of temperature on materials and devices have been of great interest throughout the history of

semiconductor research. The aim has been to investigate the high-temperature limits of materials and to enhance high-temperature semiconductor device performance. The development of semiconductor devices for reliable operation for an extended period at high temperatures is a complex process in which a number of physical effects connected with increasing temperature [24.1, 2] have to be considered. The term high temperature is not defined in a unique way in the literature and has a different meaning depending on the semiconductor under consideration and the area of application of semiconductor devices. The definition of high temperature often cited in the literature is temperatures above 125 °C [24.2, 3], since 125 °C is frequently specified as the upper limit at which standard commercial silicon devices function properly, although tests on standard commercial components indicate that even 150 °C may be applicable for selected silicon components [24.3].

Silicon is still the dominant semiconductor and silicon devices are still being developed. The most common and cost-effective integrated circuit technology is now silicon complementary metal–oxide–semiconductor (CMOS), which is able to operate up to 200 °C. The silicon-on-insulator (SOI) technology extended the operational temperature of CMOS circuits to 300 °C [24.4–8]. In addition, devices based on gallium arsenide and related alloys, which are commercialized to a lesser degree than silicon, are also candidates for high-temperature operation beyond 300 °C. The short-term operation of GaAs devices at temperatures as high as 500 °C has been reported [24.9, 10].

A survey of the literature indicates that 300 °C can be regarded as a dividing point from several standpoints, e.g. packaging, wiring, connecting, etc. [24.1, 2, 4]. This temperature is approximately the maximum temperature at which low-power silicon or conventional gallium arsenide devices can function reliably. The intrinsic carrier concentration for several semiconductors as a function of temperature is shown in Fig. 24.1. The control of the free-carrier concentration is vital for the performance of all semiconductor devices. The intrinsic carrier concentration (n_i) is exponentially dependent on the temperature:

$$n_i = \sqrt{N_C N_V} e^{-E_g/2k_B T}, \quad (24.1)$$

where E_g is the band gap, k_B is Boltzmann's constant and T is the temperature in Kelvin. Evidently, at temperatures above 300 °C, SiC, GaN and diamond and AlN have much lower intrinsic carrier concentrations than Si

Fig. 24.1 Intrinsic carrier concentration as a function of temperature of several semiconductors. (After [24.9])

and GaAs. This implies that devices designed for higher temperatures should be fabricated from wide-band-gap semiconductors to avoid the deteriorating effects of thermally generated carriers.

The wide-band-gap third-generation semiconductors, SiC and GaN (including the III–nitride systems e.g. AlGaN), have been recognized for over three decades as materials which are well suited for high-temperature electronics and for light emitters, but until recently, the low material quality has not allowed the production of high-quality devices. The availability of single-crystal SiC wafers at the start of the 1990s initiated a great deal of activity towards the development of SiC-based devices, and their commercialization started with the release of blue light-emitting diode (LED). The availability of commercial high-quality substrates meant that more research has been carried out on SiC than on the GaN and III–nitride systems. The SiC devices have the advantages of a more mature semiconductor material growth and device fabrication technology. Furthermore, GaN and III–nitride crystals have mostly been grown by heteroepitaxy on e.g. sapphire and SiC, since a viable GaN substrate technology does not exist. Unfortunately, GaN crystals always contain more defects than SiC and the current aim is to reduce the surface defect densities in GaN from current densities of the order 10⁸ cm⁻² to 10⁵ cm⁻². The unavailability of low-defect-density substrates and defect-free material limits the ability to fabricate high-quality GaN devices. The discussion of wide-band-gap semiconductors must mention AlN since it has one of the largest band gaps (wurtzite: 6.23 eV, and zincblende: 6.0 eV [24.11]). The growth of defect-free AlN crystals (as with the GaN) is an outstanding issue.

The reduction of the defect density and the effects of specific defects of third-generation semiconductors are the most urgent current problems that must be solved. Diamond is a future-generation semiconductor which is at a different stage of research than the third-generation semiconductors, particularly SiC, which is far more developed than diamond.

The research in wide-band-gap semiconductors has been driven by the need for light emitters, high-temperature and high-power industrial applications, and microwave power applications. A variety of applications e.g. in aircraft and space systems, automotive electronics, deep-well drilling, energy production centers etc., would benefit from power devices that function at high temperatures [24.12–16]. When the ambient temperature is too high, the performance-enhancing electronics presently used beneficially to monitor and control crucial hot sections must reside in cooler areas, this is achieved

by their remote location or actively by cooling with air or liquids. These thermal management approaches introduce additional overheads that can have a negative impact relative to the desired benefits when considering the overall system performance. The additional overhead, in the form of longer wires, more connectors and plumbing for the cooling system, can add undesired size and weight to the system, and increased complexity that corresponds to an increased potential for failure. The economic benefits of high-temperature electronics for various systems are likely to be orders of magnitude greater than the total market for actual high-temperature electronics. The world market for high-temperature electronics between 2003–2008 is predicted to increase from 400 to 900 million US dollars, which is substantially lower than the world's total semiconductor electronic market [24.1]. The situation can be dramatically described as follows, a mere handful of high-temperature electronic chips that may cost a few hundred dollars, can optimize the performance of a very large number of systems, thus saving many millions of dollars, e.g. deep-well drilling [24.5].

A survey of the potential industrial users of high-temperature electronics revealed that the majority of applications for high-temperature electronics operate in the range 150–300 °C [24.1, 2, 4]. The recent development of silicon and gallium arsenide electronics and their cost (silicon technology is much cheaper than SiC), indicates that wide-band-gap semiconductor devices are unlikely in the near future to be used in low-power electronics applications for temperatures up to 300 °C. These devices maybe used for application which cannot be satisfied by available technologies such as SOI, and for temperatures above 300 °C. However, in order to realize viable low-power SiC devices for the temperature range 300–600 °C, long-term reliability of electronic circuits must be achieved [24.1].

The performances of silicon power devices have almost reached their theoretical limits [24.17]. The practical operation of Si power devices at ambient temperatures higher than 200 °C appears problematic, as self-heating due to current flow at higher power levels results in high internal junction temperatures and leakage. The overall goal for high-temperature power-electronic circuits is to reduce power losses, volume, weight, and at least the costs of the system. The continuous progress in high-temperature electronics creates a demand for unique material properties, novel processing technologies and electronic devices. The physical and chemical properties required for meeting the demands of the high-temperature and high-power applications can only be

found in wide-band-gap semiconductors, which offer a number of advantages over corresponding devices fabricated from silicon. These include higher temperature stability, higher chemical stability, higher thermal conductivity, and higher breakdown field. Various device implementations not only use these standard semiconductor parameters, but also the special peculiarities these materials exhibit, e.g. aluminium nitride and gallium nitride, unlike diamond and silicon carbide, have a direct band gap and have complete miscibility with each other and with indium nitride. This is important for the implementation of optoelectronic device since it allows the band gap to be controlled, and thus the wavelength of the spectral characteristic maximum [24.4]. The wide-band-gap silicon carbide and diamond are next discussed in this review.

The properties of silicon carbides make it an excellent material for high-power devices operating at temperatures up to 600 °C and above, and at frequencies around 20 GHz. Within power electronics, SiC has the potential to replace Si-based diodes and insulated gate bipolar transistors (IGBTs), and Si gate turn-off (GTO) thyristors, which are part of the mass market of discrete power devices in general and in converter systems in particular. The power losses in SiC switches are two orders of magnitude lower compared with Si devices, thus SiC devices have a large potential for applications in e.g. uninterrupted power systems (UPS), motor controls, etc. The maximum operating temperature of a Schottky diode in SiC may be limited by an increasing leakage currents, but active power devices for operation at high temperature has been presented. U-shaped-trench metal–oxide–semiconductor field-effect transistors (UMOSFET) made from SiC that operate up to 450 °C and thyristors (6 A, 700 V) that operate at 350 °C have been presented. Furthermore, SiC MOSFETs have been reported to operated even at 650 °C, and devices based on n-type-channel metal–oxide–semiconductor (NMOS) technology, which is an integrated operational amplifier, have been reported to work at 300 °C [24.18–22]. The properties and preparation of SiC are elucidated in the next section.

Among the wide-band-gap semiconductors, diamond has the best physical, chemical and electrical properties [24.23], unmatched by any other material. The properties of interest relevant to high-temperature high-frequency power electronics are the large band-gap energy (5.5 eV), the breakdown electric field (10 MV/cm), the carrier mobilities (≈ 2200 and ≈ 1600 cm²/V s for electrons and holes, respectively), the thermal conductivity (10–20 W/cmK), the low dielectric constant (5.5),

and the excellent resistance to radiation. Diamond can be found naturally or must be synthesized. In nature diamond occurs as single crystals only, whereas synthetic diamond can be prepared as single crystals, or as a polycrystalline or as a nanocrystalline material.

The discovery that diamond can be grown by the chemical vapor deposition (CVD) technique has opened up some of the expected applications of diamond. However, the utilization of diamond's many unique properties in electronics has so far been limited among others by the unavailability of large-area high-quality diamond and that only p-type (acceptor-type impurity) diamond with high hole densities are available today. The n-type (donor-type impurity) diamond with high electron densities would find many applications, apart from the fundamental interest to realize pn-junctions and other electronic devices in diamond. The n-type diamond is expected to be a better electron emitter for field emission, photo emission, and ion or electron impact-induced emission, and may also serve as a better inert electrode for electrochemical applications.

Nevertheless, many studies have been reported with natural, high-pressure high-temperature (HPHT) synthesized and polycrystalline CVD diamonds [24.24, 25]. The pn-junctions were formed from boron- and phosphorus-doped diamond films, and from boron- and nitrogen-doped diamond films, respectively. The diamond films with high crystalline perfection were grown epitaxially on diamond single crystals. The current–

voltage (I – V) characteristic of the boron/nitrogen pn-junction diode was studied up to 400 °C. The combination of two boron/nitrogen pn-junctions, a bipolar junction transistor (BJT) which can operate in direct-current (DC) mode up to 200 °C was fabricated. The fabrication of many types of field-effect transistors (FETs) for both DC and radio-frequency (RF) modes has crossed many important milestones. The cutoff frequency of 1.7 GHz and a maximum drain current of 360 mA/mm were measured for a metal–semiconductor field-effect transistor (MESFET) with a gate length of 0.2 μm . Recently, a FET functioning up to 81 GHz was reported by a collaboration between Nippon Telegraph and Telephone Corp. and the University of Ulm in Germany. The research groups fabricated T-shaped gates on a diamond layer with a carrier mobility of 130 cm^2/Vs [24.26]. In addition, Schottky diodes that function up to 1000 °C were fabricated from either single-crystal or polycrystalline diamond. Low-resistance thermostable resistors deposited on ceramic substrates have been investigated for temperatures up to 800 °C. The temperature dependence of the field emission of nitrogen-doped diamond films has been investigated at temperatures up to 950 °C.

There has been much progress in the fabrication of diamond-based electronic devices and several types of devices have reached an important stage in their development. However, despite these developments, diamond-based electronics is still in its infancy.

24.1 Material Properties and Preparation

24.1.1 Silicon Carbide

The properties of silicon carbide makes it an excellent material for devices operating at high temperatures (600 °C and higher), high power (4H-SiC transistor: presently RF output power on the order of 5 W/mm), and high frequency [RF through X band (5.2–10.9 GHz) potentially to K band (20–40 GHz)]. The large band gap of silicon carbides (2.2, 3.26 and 3.0 eV for 3C-SiC, 4H-SiC and 6H-SiC, respectively) compared to the band gap of silicon (1.1 eV) enables devices to function at temperatures beyond 600 °C. The very high breakdown electric field of these materials (\approx 1.8, 3.5 and 3.8 MV/cm for 3C-SiC, 4H-SiC and 6H-SiC, respectively) which are approximately 10 times higher than that of Si (0.3 MV/cm), allows a reduction of the thickness of the conduction regions (for constant doping), which

results in very low specific conduction resistance. The 4H-SiC junctions exhibit a negative temperature coefficient, with a breakdown voltage that decreases by about 8% within the temperature range from room temperature to 623 °C [24.27]. The high thermal conductivity (\approx 4–4.5 W/cmK) permits a power density increase which facilitates a more compact or much higher power per area. The high saturation velocity of all three types of silicon carbide is high (\approx 2×10^7 cm/s) compared to the value for silicon (1×10^7 cm/s). The low carrier mobilities of silicon carbide is a disadvantage which limits RF performance at frequencies above the X band. The electron mobilities are of the order 900, 500 and 200 cm^2/Vs for 3C-SiC, 4H-SiC and 6H-SiC, respectively. The hole mobilities are of the order of 50 cm^2/Vs for all three types of SiC (for Si: \approx 1350 and \approx 500 cm^2/Vs for electrons and holes, respectively). The carrier mobilities

Table 24.1 Approximate values of physical properties for some semiconductors

Name	Bandgap E_g (eV)	Maximum electric field (V/cm)	Dielectric constant ϵ_s	Thermal conductivity (W/cmK)	Carrier mobility (cm^2/Vs)
Si	1.1	3×10^5	11.8	1.5	1350 480
GaAs	1.4	3.5×10^5	10.9	0.8	8600 250
SiC	3.3	2.5×10^6	9.8	4.9	980 200
GaN	3.4	2×10^6	7.8	1.4	2000
Diamond	5.5	1×10^7	5.5	10–20	1800 1600

of SiC are adequate however, for high-power devices in the X band. The properties of silicon carbide and diamond relevant for electronics are given in Table 24.1.

Noteworthy, is that silicon carbide has a close lattice match with III–nitrides, which makes it a preferred substrate material for nitride-based electronic and optoelectronic devices. The commercial production of large substrates which have improved electronic and optoelectronic properties constitutes a milestone in their application. These materials have been used (among

others) for large-scale production of green, blue and ultraviolet light-emitting diodes. Unfortunately, unavailability of high-quality defect-free SiC substrates is slowing down the pace of transition from research and development (R&D) to production of SiC devices, which may include high-power solid-state switches or diodes for electrical power control, and high-power-density microwave transistors.

Silicon carbide occurs in a large number of polytype structures. The number of polytypes in the literature

Fig. 24.2a–d The stacking sequence of double layers of the four most common SiC polytypes, (a) locations of C atoms, labeled A, in the first biatomic layer in the {0001} plane; (b), (c) optional positions of C atoms, labeled B and C, respectively, in the next biatomic layer above the first layer; (d) first biatomic layer with six C atoms and the optional positions of the three C atoms in the next biatomic layer, (e)–(h) stacking sequence of the most common SiC polytypes. The solid line indicates the completion of the unit cell in the [0001] direction (After [24.28])

varies between 150 and 250. These polytypes are differentiated by the stacking sequence of the biatomic close-packed layers. A detailed study of silicon carbide's polytypism was done in [24.29]. The most famous polytypes are the hexagonal 4H and 6H, cubic 3C, and rhombohedral 15R structures. Not all types are easy to grow; only 4H and 6H polytypes are available as substrate materials. In a single bilayer of SiC each C atom is tetrahedrally bonded to four Si atoms – to three ones within the layer and to one in the next layer. Looking at a bilayer from the top in the direction of the *c*-axis [0001], the C atoms form a hexagonal structure, as shown in Fig. 24.2a and Fig. 24.2d. These are labeled 'A'. The C atoms of the next biatomic layer have the option to be positioned at the lattice sites 'B' or 'C', as shown in Fig. 24.2b and Fig. 24.2c, respectively. This is the stacking sequence defining a polytype. Figure 24.2d shows schematically the first bilayer, with six C atoms forming the hexagonal structure and the optional positions for the three C atoms in the next layer beyond the first layer. Figures 24.2e–h shows the stacking sequence for the most common SiC polytypes. The change in sequence has an impact on the properties of the ma-

terial, for example the band gap changes from 3.4 eV for 2H polytype to 2.4 eV for 3C polytype. Figures 24.3a–e shows the structure of the most common SiC polytypes viewed in the $\{11\bar{2}0\}$ plane, i. e. in the [0001] direction.

The leading manufacturer of substrates is Cree Inc., though new manufacturers have recently appeared. The crystalline quality in terms of a low defect density, and a specially low micropipe density the substrates of Cree Inc. are still ahead. The preparation of silicon carbide is complicated by the fact that it does not melt, it sublimates at temperature above 2000 °C, thus standard growth techniques, e.g. the Czochralski process by which large single-crystal ingots are produced by pulling a seed crystal from the melt, cannot be used. Silicon carbide crystals are grown by a sublimation method first developed by Lely in 1955 [24.30], and later extended to a seed sublimation technique by Tairov and Tsvetkov in 1978 [24.31]. This method is also termed physical vapor transport (PVD) growth. The crystals are grown by SiC deposition derived from Si and C molecular species provided by a subliming source of SiC placed in close proximity to the seed wafer.

A new high-temperature CVD (HTCVD) technique was developed in 1999 [24.28], where the growth rate can be tuned in such a way that a high-quality thick epitaxial layer with precisely controlled doping levels can be grown in a few hours, which is fast compared to conventional CVD, which takes days to grow a similar structure. As an alternative to CVD, sublimation epitaxy has also been demonstrated for the growth of thick epitaxial layers. The growth rate in sublimation epitaxy is also very high, of the order of a few hundred micrometers an hour. In devices where the control of the doping level is an important issue, sublimation epitaxy has been shown to work successfully.

The commercial availability of SiC substrates with increasing diameter and quality has been a prerequisite for advances in SiC device technology. The SiC substrates are available in two different polytypes, namely 6H- and 4H-SiC. The latter is relevant for electronic application due to its higher carrier mobility and wider band gap than 6H-SiC. SiC substrates have been in the market for over a decade, but the absence of defect-free growth is slowing the pace of transition from research and development to the production of power devices such as high-power solid-state switches or diodes for electrical power control and high-power-density microwave transistors. Three-inch 4H-SiC substrates have been commercially available since 2001, but it was only recently that their defect concentration have been reduced to levels that allows for the fabrication of com-

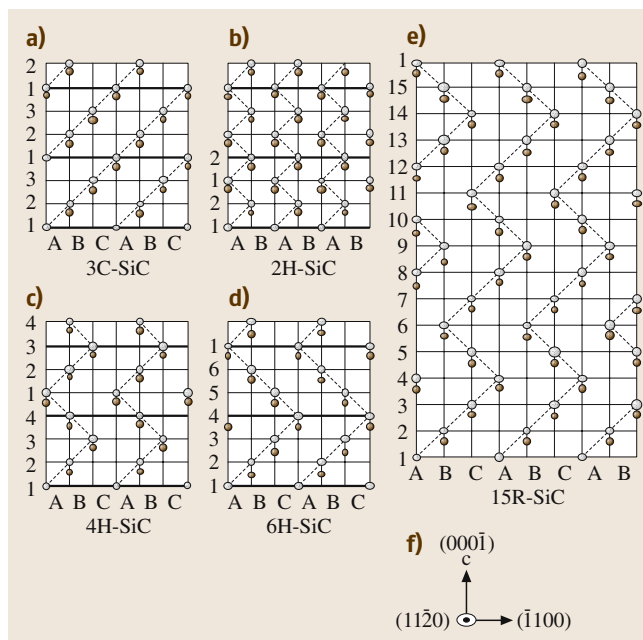

Fig. 24.3a–f Schematic representation of the structure of the most common SiC polytypes viewed in the $\{11\bar{2}0\}$ plane. The black dots represent C atoms and the open circles represent Si atoms. The bold line indicates the completion of the unit cell in the [0001] direction (After [24.28])

mercially viable high power switches. During 2003 Infineon and Cree Inc. released 10 Amps devices, which is clear evidence that substrates have reached an acceptable level of quality.

The important defects of SiC are different types of dislocations. The open core screw dislocations called micropipes are of particular concern for SiC due to their detrimental effects on power devices. Micropipes cause diodes to fail for voltages that are much smaller than the voltage at which avalanche breakdown occurs [24.33]. Progress in the development of the physical vapor deposition (PVD) technique during the last four years, has resulted in a significant reduction of the micropipe density in 3-inch 4H-SiC wafers, from a previously typical value above 100 cm^{-2} to a value as low as 0.22 cm^{-2} in R&D samples. The micropipe densities in commercially available substrates are $< 30\text{ cm}^{-2}$ and $< 80\text{ cm}^{-2}$ for n-type and semi-insulating materials, respectively. 100-mm 4H-SiC wafers are now under development. The micropipe densities for such wafers are $\approx 22\text{ cm}^{-2}$ and $\approx 55\text{ cm}^{-2}$ for n-type and semi-insulating crystals, respectively [24.34, 35].

Low-angle grain boundaries, also known as domain walls, are another class of defect that has to be reduced, since they are associated with leakage currents and failure in devices, and may cause wafers to crack during epitaxial processing. This type of defect can be observed through whole-wafer X-ray topography, though it is difficult to obtain quantifiable numbers on wafer quality by such measurements. This defect seems to be intimately related to the growth method used [24.36]. A class of defects known as threading screw dislocations are suggested to have an impact on the leakage behavior of Schottky diodes. The evidence suggests that these defects are introduced at the seed/growth interface by seed subsurface damage. The application of seed treatment reduces the density of dislocations in a 3-inch 4H-SiC wafer from a value of the order $3 \times 10^4\text{ cm}^{-2}$ to $3 \times 10^3\text{ cm}^{-2}$ [24.35]. The so-called basal plane dislocation is another important and significant defect. It has been shown that PiN device structures are susceptible to severe degradation of the forward voltage characteristics due to the presence of these defects in the active layer of the device [24.37]. The presence of these dislocations increases the resistance of the active layer of the device. It is critical to reduce the density of these dislocations in epitaxial layers for stable device production. A level of basal plane dislocations in the substrate which may be acceptable in order to allow reasonable yields of PiN diodes, is on the order of 100 cm^{-2} . The average density of the basal plane dislocations in 3-inch 4H-SiC wafers

is $1.5 \times 10^3\text{ cm}^{-2}$ [24.35]. Recently it was reported that this type and even other types of dislocations and defects can be reduced by growing the material along the *a*-face direction [24.32]. Single crystals of SiC are usually grown by the method termed *c*-face growth, where crystals are grown along the $\langle 0001 \rangle$ *c*-axis direction using a seed of $\{0001\}$ substrate. In the new method, known as a repeated *a*-face growth process, single crystals are grown along the *a*-axis $[1\bar{1}20]$ or $[1\bar{1}00]$ (both axis are called the *a*-axis in the report) direction in several steps. The *a*-face growth process is shown in Fig. 24.4.

The electrical properties of SiC substrates are related to the purity of the as-grown crystals. The substrate purity is dominated by the presence of residual nitrogen and boron impurities. The level of these impurities is critical for the production of undoped high-purity semi-insulating substrates with uniform and stable semi-insulating properties. High-purity 3-inch and 100-mm

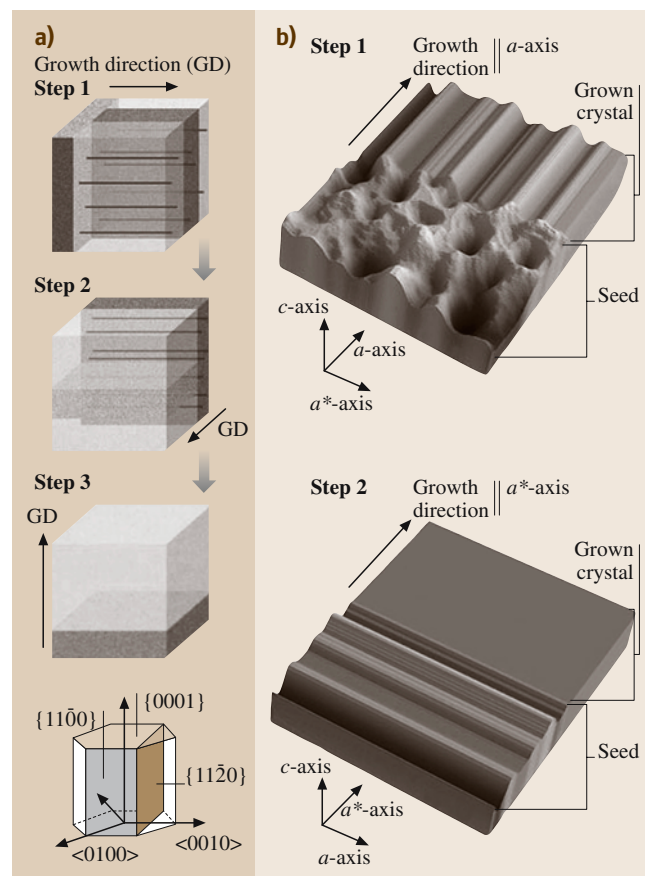

Fig. 24.4 Schematic picture of the *a*-face growth of SiC. (After [24.32])

4H-SiC substrates with low micropipe densities and uniform semi-insulating properties ($> 10^9 \Omega \text{ cm}$) over the full wafer diameter have been produced. These wafers had typical residual contamination densities $5 \times 10^{15} \text{ cm}^{-3}$ and $3 \times 10^{15} \text{ cm}^{-3}$ for nitrogen and boron, respectively [24.38].

Although most doping of SiC is obtained by an in situ method during epitaxial growth, additional selected-area doping is often required during fabrication of devices such as MOSFETs and lateral bipolar transistor. Due to the extremely low diffusion coefficient of dopant atoms in SiC even at very high temperatures ($\approx 2000^\circ\text{C}$), ion implantation is the only viable doping technique during device fabrication. The critical parameters of ion implantation of dopants in SiC are the temperature of SiC during implantation (from room temperature up to 900°C), as well as the subsequent annealing required to activate the dopant, performed at around 1700°C . Nitrogen is typically used as the n-type dopant, while Al is often the p-type dopant widely used during epitaxy. The element boron is a lighter element than Al and subsequently causes less lattice damage during implantation, and may eventually replace Al. However, a small amount of B also diffuses into the lightly doped drift-layer side during the annealing process, thereby degrading the junction.

The high bond strength of SiC means that room-temperature wet etches for this material do not exist, and so reactive-ion etching (RIE) is the standard method used. Frequently fluorine-based chemistries are used in which the silicon forms a volatile SiF_4 molecule and C is removed either as CO_2 or CF_4 . However, RIE is not regarded as a limitation since, as feature sizes decrease, dry etching processes are actually preferred to wet etching.

A unique advantage of SiC compared to other wide-band-gap semiconductors, is its ability to oxidize and form SiO_2 exactly as in Si technology. The oxidation rates are much lower for SiC than for Si, and are very dependent on if a silicon- or carbon-terminated face is exposed to the growing SiO_2 . The fabrication of high-quality thermal oxides with low interface state and oxide-trap densities has proven to be a great challenge. Finally, the reliability of oxides is a major issue for SiC devices since, at high electric fields and high temperatures, oxides have poor longevity. This issue needs further research to reduce the leakage current in the devices that operate at elevated temperatures.

An important issue in high-temperature electronics is the type of metallization used, where examples include ohmic, Schottky, heat-sinking and capping.

It is necessary to have reasonable thermal expansion matching and good adhesion between the metal and SiC. The wide band gap of silicon carbide makes it difficult to control the electrical properties at the metal–semiconductor interface of devices. In addition, stable noncorrosive contacts are also key issues in high-temperature electronics. The main parameter of concern for SiC high-frequency devices is a stable Schottky barrier for good rectification and a low reverse leakage current while operating at elevated temperatures. Several groups have tried different combinations of transition metals that form good Schottky contact on n- and p-type SiC with barrier heights in the range $0.9\text{--}1.7 \text{ eV}$ [24.20, 39–41]. The rectifying properties either change to ohmic or degrade severely while operating at temperatures above 600°C . Among the ohmic contact the most widely used material for n-type is Ni_2Si which is generally formed by deposition of Ni film and silicidation is obtained by annealing at above 900°C . The Ni_2Si ohmic contact has been shown to be stable at very high temperatures [24.39, 42]. The formation of low-resistance ohmic contacts to p-type SiC is still difficult since metals with sufficiently large work functions are not available to offset the wide band gap and electron affinity of SiC. Aluminum is typically used to form p-type ohmic contacts. A major drawback of Al however is its relatively low melting point, which prohibits its use for high-temperature applications. Several other combinations of different metals have also been reported in the literature these have poor contact resistivities compared to Al [24.43, 44]. A special effort is required to develop stable contacts for SiC devices operating at higher temperatures, and metals with a high melting temperature and their silicides and carbides should be studied in the future towards this goal.

The packaging of SiC devices for high-power and high-frequency applications and operation at elevated temperature is an issue that has been neglected compared to material growth and device processing technology. It is highly desirable to find suitable packaging for high-temperature electronics which can endure high thermal stress and high power without the extra effort of cooling.

24.1.2 Diamond

Among the wide-band-gap semiconductors, diamond has the best properties, unmatched by any other material [24.45–49]. Most electrical, thermal and optical properties of diamond are extrinsic, i.e. strongly dependent on the impurity content [24.23, 46], the most common impurity being nitrogen. Diamond has

a large band gap (5.5 eV), high breakdown electric field (10 MV/cm), low dielectric constant (5.66–5.70), high carrier mobilities (≈ 1800 and $\approx 1600 \text{ cm}^2/\text{Vs}$ for electrons and holes, respectively [24.45]), high saturated carrier velocity ($2.7 \times 10^7 \text{ cm/s}$ and $1 \times 10^7 \text{ cm/s}$ for electrons and holes, respectively), high thermal conductivity (10–20 W/cmK), high resistivity (10^{13} – $10^{16} \Omega \text{ cm}$), low thermal expansion coefficient (1.1 ppm/K at room temperature), the highest sound velocity ($1.833 \times 10^6 \text{ cm/s}$), exceptional hardness ($10\,000 \text{ kg/mm}^2$) and wear resistance, low friction coefficient (0.05, dry), broad optical transparency [from 225 nm to far infrared (IR)], excellent resistance to radiation, chemical and thermal stability. A unique feature of diamond is that some of its surfaces can exhibit a very low or negative electron affinity. Obviously diamond is the material of choice for many applications, including electronics. The properties of diamonds make it the most suitable semiconductor for power electronics at high (RF) frequencies and high temperatures [24.50–53]. Since diamond-like silicon is a single-element semiconductor it is less susceptible to have the high density of structural defects that are usually present in compound semiconductors. However to date, diamond is regarded as one of the most difficult semiconductors to synthesize for the fabrication of electronic devices.

Diamond is a cubic semiconductor with lattice constant $a = 3.566 \text{ \AA}$. The covalent bonding of the carbon atoms (sp^3 bonds) is extremely strong and short, which gives diamond its unique physical, chemical and mechanical properties [24.46–49]. Diamond is available naturally and can also be synthesized. The natural form of diamond occurs as single crystals, whereas synthetic diamond can be prepared as single crystals, or as polycrystalline or nanocrystalline material. Usually natural diamond single crystals have a high nitrogen content and cannot be used for the fabrication of electronic components. The natural form of diamond has been classified according to several criteria, a detailed description of the classification of diamonds has been given by Walker [24.46] and Zajtsev [24.54].

Diamond melts at approximately 3827°C [24.45]. It is stable at elevated temperatures, but the stability depends on the ambient. In hydrogen ambient diamond is stable up to 2200°C [24.55], but it is graphitized in vacuum [24.56, 57] or in an inert gas [24.56]. Diamond does not have a native oxide, but it oxidizes in air at elevated temperatures. This is a critical point for the application of diamond for high-temperature devices. The oxidation of natural and synthetic diamond has been studied since the beginning of the 1960s; despite this

more research is needed for a complete understanding of the oxidation process. The activation energy for the oxidation of CVD-grown films in air was 213 kJ/mol for temperatures of 600 – 750°C and the oxidation proceeded by etching pits into the CVD film, thus creating a highly porous structure [24.58]. The results of several studies indicated that diamond oxidized preferentially. The oxidation of natural diamond and CVD-grown diamond films in oxygen has been observed to be dependent on the crystallographic orientation, here the (111) plane oxidized more easily than the (100) and (220) planes, and also the CVD films were less resistant to oxidation than natural diamond [24.56, 59]. Sun et al. [24.56] observed that the oxidation of synthetic diamond started in air at 477°C when oxygen is able to impinge into the densely packed (111) planes and they suggested that the oxidation of diamond occurs by the same mechanism as the corrosion of metals, whereby oxygen penetrates into the bulk by bonding and rebonding, leaving behind weakly interacting dipoles which are eroded away during processing. Lu et al. [24.60] reported that the oxidation in air of diamond films prepared by DC arc plasma jet started at 650°C which was about 100°C lower than the temperature of oxidation of natural diamond. Furthermore, it was reported that the oxidation rate of CVD diamond depended on the diamond's growth condition [24.61].

There are several etchants for diamond; the most commonly used method is oxidative etching. The effects of dry oxygen and a mixture of oxygen and water in the temperature range 700 – 900°C has been studied and compared with the effect of molten potassium nitrate [24.62, 63].

Diamond-based electronic devices have now been fabricated from natural and synthesized single crystals, high-purity single-crystal films (homoepitaxial diamond), and from polycrystalline films (heteroepitaxial diamond). Single crystals can be synthesized artificially by the high-pressure high-temperature method (HPHT), which mimics the process used by nature. The drawback of this method is that it produces single crystals limited in size. The largest crystals prepared by this method have a dimension of the order of millimeters, and the processing time to produce such crystal is very long [24.64]. These crystals have been used for the fabrication of discrete electronic devices and as substrates for homoepitaxial growth of diamond films by CVD technique. Diamond films have been epitaxially deposited on diamond single-crystal substrates, this demonstrates that single-crystal diamond deposition is possible by low-pressure processing [24.65, 66].

The discovery that diamond can be grown homoepitaxially and heteroepitaxially by the chemical vapor deposition (CVD) technique has opened up some of the expected applications of diamond. The history of this technique goes back to the late 1960s. During the 1980s, researchers [24.67, 68] made a series of discoveries which enabled them to grow, at significant growth rates, diamond films of high quality on non-diamond substrates by using hot-filament CVD and subsequently by microwave plasma chemical vapor deposition (MPCVD). This started a worldwide interest in diamond CVD for both research and technology. Since then a number of low-pressure CVD techniques have been developed [24.69, 70] and the volume of research on the preparation of large-area diamond films has been immense.

It has been shown recently [24.71, 72] that homoepitaxial growth of diamond films on high-quality HPHT diamonds can produce single-crystal films of a purity that exceeds the purity of the purest diamonds found in nature. The measurements of the carrier mobilities in these films have revealed interesting results, such as mobilities of 4500 and 3800 cm²/Vs for the electrons and holes, respectively. These values are the highest ever reported for diamond and are approximately twice as high as those found in pure natural diamond. The carrier mobility measurements were performed on homoepitaxial diamond deposited by a microwave plasma-assisted CVD technique and a HPHT diamond single crystal of dimensions 4 × 4 × 0.5 mm was used as the substrate. The homoepitaxial diamond film was found to be of exceptional purity and was found to contain a low concentration of intrinsic and extrinsic defects. The total measured nitrogen concentration was less than 1 × 10¹⁵ cm⁻³ and the dislocation density was less than 1 × 10⁶ cm⁻². The exceptionally high values of the carrier mobilities were attributed to the low defect and dislocation densities.

The disadvantage of diamond homoepitaxy is that only small-area single crystals can be fabricated, and substrates typically have a size of the order of millimeters. In order to exploit diamond's superior properties for the fabrication of electronic devices, thin diamond films are required, i.e. a method for the production of large-area, inexpensive single-crystal films with a low defect density.

Despite the progress made, the available diamond homoepitaxy methods cannot solve the technological problem of producing large-area diamond wafers for the fabrication of electronic devices. During the last 10 years film preparation has focused on diamond heteroepitaxy. The aim has been to produce films of homoepitax-

ial diamond's quality by avoiding the formation of grain boundaries and other defects. The research has focused on finding suitable substrates, conditions for achieving high diamond nucleation densities on various substrates, and the optimization of textured growth procedures. To date many substrates have been investigated, e.g. Ni, Co, Pt, Si, BeO, SiO₂, cubic BN, β -SiC, GaN, etc. [24.73–77]. Although some of these materials are suitable substrates, e.g. BN [24.77], all attempts to grow large diamond single-crystal films have hitherto failed. Most of the CVD diamond films reported to date have been grown on Si, mainly due to the availability of large-area single-crystal wafers and the low cost of Si as well as the favorable properties of Si [24.78–84]. These films are still polycrystalline but highly oriented (HOD) with respect to the substrate and have found application in many fields, e.g. electrochemical electrodes, field-emitter arrays, radiation detectors, micro-electromechanical systems (MEM), etc. In the field of MEMS a large number of devices for various applications have already been built, demonstrating thus the excellent properties of these films [24.85–87]. Despite their high quality, these films are not suitable for the fabrication of electronic devices since their attractive properties are deteriorated by structural imperfections, particularly by grain boundaries. The performance of electronic devices fabricated using such low-quality films is significantly reduced. Furthermore, due to their mosaic spread, these films cannot be used as substrates for the homoepitaxial growth of diamond.

A significant advance in diamond heteroepitaxy was made by the application of substrates with a multilayer structure. It was discovered that iridium single-crystal films grown as a buffer layer on MgO could serve as a substrate for the nucleation and growth of low-pressure microwave plasma-enhanced CVD diamond [24.88, 89]. The substrate MgO was later replaced by SrTiO₃ [24.90, 91], which decreased the mosaic spread of the epitaxial iridium and of the resulting heteroepitaxial diamond. The diamond layer had single-crystal quality and was used for the fabrication of field-effect transistors [24.92]. A further advance in the large-scale heteroepitaxial growth of diamond has been made recently when SrTiO₃ was replaced successfully by sapphire [24.93, 94]. Diamond produced in this way had the same high quality as that prepared on SrTiO₃. However, since sapphire is a relatively inexpensive large-area substrate, this development is a further step towards the wafer-scale production of heteroepitaxial diamond.

When cooling from the growth temperature the diamond film experiences significant compressive stresses

due to the difference in the thermal expansion coefficient of the materials present. These stresses can cause delamination, which is a serious obstacle for the development of diamond wafers. Moreover, calculations have shown [24.95] that films grown on MgO, SrTiO₃ and α -Al₂O₃ substrates are exposed to a significant amount of stress, -8.30 , -6.44 and -4.05 GPa, respectively. These large stresses make the treatment of thick films difficult. From the thermal stress point of view, Si with a stress of -0.68 GPa is the best substrate so far.

Further step towards the fabrication of large-area diamond single-crystal films for electronic applications has been made recently [24.95] by introducing a new concept for the substrate multilayer. The multilayer was prepared in two steps, where yttrium-stabilized zirconia (YSZ) was first deposited on Si, then an iridium thin film was deposited on the YSZ. This process decreases the lattice misfit between consecutive layers and such a substrate multilayer is shown in Fig. 24.5. The diamond was then grown on the iridium film as before. The quality of the diamond was the same as of that grown on SrTiO₃. The advantage of this concept is in the type and the combination of the substrate materials, which minimizes thermal stress thereby avoiding delamination.

In order to exploit diamond's superior properties for the fabrication of electronic devices, thin diamond films are required, i.e. a method for the production of large-area inexpensive single-crystal films with low

Fig. 24.5 Schematic representation of the layer system diamond/Ir/YSZ/Si(001). In the YSZ crystal the *large spheres* correspond to the oxygen ions. The *numbers* indicate the lattice mismatch between consecutive layers. (After [24.95]) (Figure provided by Mathias Schreck, University of Augsburg)

defect and dislocation densities is needed. Diamond device technology has similar problems to third-generation semiconductor technology, namely, the availability of inexpensive large-area diamond crystal with a low defect concentration; this is the prerequisite for a successful application of diamond for the fabrication of electronic devices.

24.2 Electronic Devices

24.2.1 Silicon Carbide

The ability of silicon carbide to operate at high temperature, high power, and high frequencies enables considerable enhancement of the performance of devices used within a wide variety of applications. In particular, SiC power devices can outperform equivalent Si devices, but this would require a mature and viable SiC semiconductor technology. The fundamental physical limitations of Si operation are the strongest motivation for switching to a wide-band-gap semiconductor such as SiC for high-temperature applications. The replacement of Si by SiC for power switches [24.20] is extremely advantageous, since the avalanche breakdown voltage for SiC is about ten times higher than that of Si (see Fig. 24.6 and Fig. 24.7). Moreover, silicon-carbide-based power switches also have a faster response with a lower parasitic resistance, so that the physical size of SiC devices

will be much smaller than equivalent silicon devices. In addition, the faster switching speed enhances the efficiency of power system conversion, and allows the use of smaller transformers and capacitors, which reduce significantly the overall size and weight of the system. The cooling requirements in power electronics, which are a considerable portion of the total size and cost of power conversion and distribution systems, can be significantly reduced by the high-temperature capabilities of SiC.

Power switching devices based on SiC such as Schottky barrier diodes, PiN junction diodes, metal-oxide-semiconductor field-effect transistors (MOSFETs), junction field-effect transistors (JFETs), bipolar junction transistors (BJTs) have already been demonstrated in the research stage. To date, SiC Schottky barrier diodes used for high-voltage applications have evolved from the research stage to limited commercial production [24.96]. Although Schottky barrier diodes offer rectification with

lower switching losses compared to PiN diodes (when switching from the conducting state to the blocking state) Si-based Schottky barrier diodes are still not used for high-voltage applications. The reason for this is the comparatively lower barrier height between ordinary metals and Si (typically less than 0.5 eV), which is further reduced in reverse-biased mode. The electron injection current from metal to semiconductor increases exponentially as the barrier height reduces. As a result very large reverse currents are observed at relatively low voltages, in the case of Si. The high Schottky barrier height of about 1.5 eV for SiC reduces the leakage current such that SiC Schottky diodes can operate at high voltages, and a blocking voltage of up to 5 kV has been demonstrated [24.39].

Diodes, Schottky and PiN Diodes

In contrast to Si diodes, SiC rectifiers exhibit ultimate low switching losses, no reverse current peak, and therefore an extreme soft recovery behavior. In Schottky diodes, a reduced forward-voltage drop and hence a reduced power loss would be desirable, and this can be achieved by lowering the Schottky barrier height. On the other hand, even at high temperatures, the barrier must be high enough to ensure a certain blocking voltage with a reasonably low reverse-leakage current. There is a strong dependency of the measured reverse current on the electric field for a Ti/SiC Schottky diode, with the temperature as a parameter [24.98].

Schottky barrier diodes with Ta and TaC on p- and n-type SiC have been investigated by a group at Carnegie

Mellon University [24.99]. The rectifying behavior of both Ta and TaC was observed on p-type 6H-SiC to 250 °C, while on n-type, TaC showed ohmic behavior above 200 °C [24.99]. The maximum operating temperature of SiC Schottky diodes is restricted because of the increasing leakage current and therefore, junction devices can approach and perform better at higher temperature.

The pn-junction diode characteristics at temperatures up to 400 °C have been reported both for epitaxially grown and ion-implanted SiC. The characteristics of the 6H-SiC pn-diode were obtained where nitrogen was implanted into p-type substrate. The rectifying ratio was measured to be 10^9 at room temperature and 10^5 at 400 °C. PiN diodes of 4H-SiC have been successfully fabricated and this device has a blocking voltage of up to 19 kV [24.100]. The high-temperature operation of a 8-kV diode indicates that the reverse leakage current density at 5 kV increases by only an order of magnitude between room temperature and 300 °C [24.101]. The reverse recovery of these diodes showed an extremely fast switching, which only increased by a factor of two between room temperature and 275 °C. This is small compared to Si diodes, which have an increase of four times between room temperature and 120 °C [24.101]. In the 5.5-kV blocking range of a PiN diode, a forward voltage drop of less than 5 V was observed at 500 A cm^{-2} between room temperature and 225 °C, in addition to a 50% increase in the peak reverse recovery current [24.102]. The reverse leakage current in a large-area ($6 \times 6 \text{ mm}^2$) diode which blocked 7.4 kV showed a small increase in the current up to 200 °C after packaging when measured up to 4.5 kV [24.103].

Another diode, the so-called junction barrier Schottky (JBS), is also considered an attractive device for power switching applications. The JBS device was first demonstrated in Si [24.104, 105]. The device structure is a combination of a Schottky barrier and a pn-junction, which allows a reduction in the power loss of the pn-junction under forward conduction and the utilization of the Schottky barrier. In the reverse direction the Schottky region is pinched off by the pn-junction, thus exhibiting a smaller leakage current. The spacing between the p^+ regions should be designed so that pinch-off is reached before the electric field at the Schottky contact increases to the point where excessive leakage currents occur due to tunneling, this complicates the device design and several attempts have been reported [24.106–108]. The major problem concerning SiC may be the poor ohmic contact with p-doped samples, which requires very-high-temperature

Fig. 24.6 Comparison of silicon carbide and silicon dielectric strength. (After [24.97])

annealing (above 850 °C) that causes severe damage to the Schottky contact; this then increases the excessive leakage current compared to an undamaged Schottky contact.

Though all these results on PiN diodes are very encouraging, there still remain problems in their practical operation. The most important perhaps, is the degradation of the current with time when operating under forward bias. One of the most attractive applications of SiC PiN diodes is in high-voltage DC (HVDC) electrical transmission systems. The current degradation is presumed to be related to the generation and extension of stacking fault defects in the basal plane. These defects lie in the crystalline plane perpendicular to the current flow direction. Recently it has been claimed [24,109] that this problem may be solved by growing the material along another direction. In order to get a defect-free crystalline structure, the material was grown on several *a*-face surfaces in at least 2–3 steps. The PiN diodes fabricated from this material were stressed and measured for 4 h at constant voltage. Growth using a few steps might be not feasible and more research on the operation of these PiN diodes is needed.

High-frequency MESFETs, SITs and BJTs

Concerning high-frequency devices, several groups from the USA, Japan and Europe have demonstrated two types of SiC transistors, metal–semiconductor field-effect transistor (**MESFETs**) and static induction transistors (**SITs**). These transistors suffer from large gate leakages, so that the possible application may be restricted to less than 350 °C. Static induction transistors (**SITs**) shows the best performance for high-peak-power applications up to 4 GHz. Under class C operation, the transistor produces over 350 W output power with 50% efficiency and a gain greater than 10 dB [24.110]. At ultra-high frequency (UHF) 900 W, pulsed power was obtained from a single chip packaged with a 51-cm gate periphery at L-band, and the same power was obtained for a 54-cm periphery package [24.110]. No investigations of the thermal limit of the high-temperature operation have been reported for such high-power **SITs**. For **MESFETs**, power densities as high as 5.2 W/mm² with 63% power added efficiency (**PAE**) have been demonstrated at 3.5 GHz while single device with 48 mm of gate periphery yielded 80 W continuous wave (CW) at 3.1 GHz with 38% **PAE** [24.111, 112]. Though these results are impressive, the transistor performance suffers severely from self-heating due to current flow in the device. Thus the majority of published articles are related to the small-gate periphery since thermal prob-

Fig. 24.7 Comparison of silicon and silicon carbide operating voltage and conduction resistance. (After [24.20])

lems are limited and the power densities are recorded to be very high. When the gate periphery increases, the power densities decrease very quickly, this is related to the self-heating effect. For a wide transistor, the temperature becomes very high and, therefore, the electron mobility decreases together with the drain current, and finally the **RF** power decreases. In a recent investigation, a channel temperature as high as 340 °C was observed for a large 31.5-mm transistor when only **DC** biases without any **RF** excitation was applied; the estimated dissipated power was 58.6 W in class AB [24.113]. In another investigation, the saturated **DC** drain current was reduced from 80 mA to 50 mA when the temperature was increased to 250 °C for a 6H-SiC **MESFET** [24.114].

Very little work has been published so far on bipolar transistors and specially within microwave applications. Due to the wide band gap, junctions of the transistors can control the reverse and forward current, and hence can be very attractive for high-ambient-temperature operations. However, the transistor suffers from some severe materials properties such as low minority-carrier lifetime, a very small hole mobility that restricts the cutoff (f_T), and a maximum frequency of oscillation (f_{max}).

The transistors have been fabricated and exhibited typical emitter breakdown at 500 V while the f_T was only 1.5 GHz. A transistor with an emitter width of 2.5 μm and an emitter periphery of 2.62 cm has demonstrated an output power of 50 W using a 80 V power supply in common-emitter class AB mode. The pulse width was 100 μs and the duty cycle was only 10%. The collector efficiency was 51% with a power gain of 9.3 dB [24.115]. Since SiC junctions can withstand high junction temperatures, the transistor can function efficiently without any external cooling, resulting in significant system advantages.

JFETs

SiC-based JFETs are very attractive for high-temperature electronics for the reasons described for BJTs. JFETs are more attractive as they are unipolar devices and thus do not suffer from a low value of the hole mobility. However, JFETs are normally depletion-mode (normally on) devices, and the gate must be kept at a negative voltage to keep the transistor off. Most power control systems require enhancement-mode (normally off) transistors so that the system can be switched off in a safe condition. One way to circumvent this problem is to connect a JFET in a cascode configuration with an enhancement-mode control device such as a Si or SiC MOSFET [24.116]. High-temperature operation of SiC-based JFETs has been reported in the literature since the early 1990s along with the evolution of SiC as a semiconductor for microelectronics.

Transistors with high blocking voltage up to 5.5 kV have been successfully fabricated. This transistor showed a specific on-resistance of 69 $\text{m}\Omega\text{ cm}^2$ and the turn off time was 47 ns [24.117]. The material 4H-SiC is more attractive due to high carrier mobilities which results in some favorable properties. Specifically, in a vertical JFET with the drain on the back side of the wafer, the forward current density reached 249 A/cm^2 at a drain voltage of only 1.2 V at room temperature, while at 600 °C the current dropped to 61 A/cm^2 with an increase of the specific on-resistance from 4.8 to 19.6 $\text{m}\Omega\text{ cm}^2$. In addition, the breakdown voltage of the transistor was 1644 V at room temperature, while it increased to 1928 V at 600 K [24.118]. In a thermal stress study of a 6H-SiC JFET, a decrease of about 40% in the drain current was observed at 300 °C [24.119].

High performance of SiC JFET has been reported by Siemens. The buried gate is permanently connected to the source, and the device blocked 1800 V at a specific on-resistance of 24 $\text{m}\Omega\text{ cm}^2$. Recently, Kansai Electric

and Cree Inc. reported the first enhancement-mode SiC JFET [24.120]. The device structure consisted of two gates; the buried gate was connected to the top gate, providing a gating effect from both sides. The transistor with a 50- μm -thick drift layer blocked 4.4 kV and the specific on-resistance was 121 $\text{m}\Omega\text{ cm}^2$.

MOSFETs

In contrast to Si MOSFETs, the 6H-SiC MOSFETs transconductance and channel mobility increases with rising temperature up to 225 °C. The high interface state density [24.121] may be the reason for these trends. MOSFETs fabricated from 6H-SiC have operated at temperatures around 400 °C with a very low drain leakage current in air [24.122]. In a recent report, a large-area device (3.3 mm \times 3.3 mm) blocked 1.6 kV with an on-resistance of 27 $\text{m}\Omega\text{ cm}^2$. This device exhibited a peak channel mobility of 22 cm^2/Vs and a threshold voltage of 8.8 V, which decreased to 5.5 V at around 200 °C [24.123].

The transistors were fabricated both in the lateral double-diffused MOSFET (DMOSFET) and the vertical U-shaped-trench MOSFET (UMOSFET) directions, these blocked several kilovolts. The Northrop Grumman group determined that both transistor types have similar channel mobilities and the same temperature effect due to the interface traps. In addition, they operated at up to 300 °C where the current and transconductance increased with rising temperature [24.124]. A group at Purdue University demonstrated a novel DMOSFET which could block 2.6 kV, where the drain current at 155 °C was four times the value at room temperature [24.125]. Recently, Purdue and Auburn University fabricated a UMOSFET that could block more than 5 kV, with a specific on-resistance of only 105 $\text{m}\Omega\text{ cm}^2$, for a 100- μm -thick low-doped drift layer (see e.g. Fig. 24.7). This device has not been characterized at elevated temperatures [24.126]. The transistor maintained a low on-resistance to current densities above 100 A/cm^2 , while the maximum reported current density was 40 A/cm^2 . Cree Research has already reported a record blocking of more than 6 kV.

Due to the problems caused by a high interface-state density, which results in a very low channel mobility, a new type of transistor, the accumulation-mode MOSFET (ACCUFET), with output characteristics that are similar to MOSFETs has been introduced and fabricated in both 6H- and 4H-SiC [24.127]. The 4H-SiC transistor exhibited a high specific on-resistance, 3.2 $\Omega\text{ cm}^2$ at a gate bias of 5 V, which reduced to 128 $\text{m}\Omega\text{ cm}^2$ at 450 K. The transistors were not de-

signed for high blocking voltages thus the unterminated breakdown voltage was only 450 V.

Recently, encouraging results from the continuing research into 4H-SiC MOSFET has been reported [24.128, 129]. Growing the gate oxide in N₂O ambient results in a significant enhancement of the inversion channel mobility in lateral n-channel Si face 4H-SiC MOSFETs. A mobility of 150 cm²/V s was obtained, whereas a value below 10 cm²/V s was obtained when growing the gate by the conventional process: in a wet or dry oxygen ambient.

Thyristors, GTOs and IGBTs

One of the most significant developments in device technology during the last 15–20 years is the insulated gate bipolar transistor (IGBT), which blocks high voltages but at the same time has a high conduction current. The basic advantage of the IGBTs is conductivity modulation due to carrier injection and a MOS-driven gate. The device operates between 600 and 6.5 kV where the current varies over 1–3500 A. The device has a big potential for further development in the areas of higher currents and voltages, and for higher frequencies and lower dissipated power.

A large amount of effort is being made on the development of SiC thyristors and IGBTs. The main advantage is the high electric breakdown field strength, which leads to very thin drift layers, and consequently much faster switching behavior.

The thyristor is the most popular controllable device used in high-power systems with controllable turn-on, and large-area Si thyristors are produced today as a single device on a wafer with a 4-inch diameter. The current capability is more than 1000 A with a blocking voltage approaching 10 000 V. These devices are used in high-voltage DC (HVDC) transmission systems, and so far no other device can match its performance. A 6H-SiC polytype thyristor was first demonstrated in early 1993. Due to the high resistivity of the p-type substrate, a high specific on-resistance of 128 mΩ cm² has been obtained for a 100 forward blocking voltage device [24.130]. However, at a higher temperature of 633 K, the thyristor performance improved with a specific on-resistance reduced to only 11 mΩ cm². The opposite polarity thyristor has been realized on the same structure with an improvement in all the characteristic parameters, and a very low specific on-resistance of about 3.6 mΩ cm² that increased to 10 mΩ cm² at 623 K temperature. Furthermore, early 4H devices exhibited a blocking voltage of –375 V. The low on-resistance of the 4H devices resulted in a lower voltage drop. Subse-

quently, the Northrop Gramman group has demonstrated a gate turn-off (GTO) with 1-kV blocking, but the device was turned-off by an external MOSFET. The device has been operated successfully at 390 °C [24.131]. Recently remarkable effort has been put into this area and 4H-SiC-based GTOs have been demonstrated with a 3.1-kV forward blocking capability with a 12-A conduction current [24.132].

24.2.2 Diamond

The many exceptional properties of diamond make it a very attractive material in several fields of electronics, optoelectronics and micro-electromechanical devices. Since an exhaustive review on the application of diamond in electronics and optoelectronics would be beyond the scope of this relatively short review, here the survey is limited to the application of diamond for pn-junctions, BJTs, FETs, passive components, heat-spreading elements, field emission, and resistors. For the application of diamond in other areas, e.g. sensors and detectors [24.133–139], microwave filters [24.140], acoustic wave filters [24.69, 141] and electro-mechanical microdevices [24.86, 142], the interested reader is directed to the above references.

pn-Junction

In order to exploit the superior properties of diamond for high-power/high-temperature electronic devices, high-quality inexpensive diamond must be available. The preparation of heteroepitaxial diamond is viable by bias-enhanced nucleation of iridium single-crystal film on sapphire or SrTiO₃ followed by low-pressure plasma-enhanced chemical vapor deposition. The crucial factor in the fabrication of electronic devices is the ability to prepare pn-junction, i.e. the ability to prepare in a reliable way p- and n-type materials with high carrier densities.

The p-type diamond has up to now been created by doping with boron. The boron is introduced from a gas or a solid [24.143–147] during diamond growth. The activation energy of electrical resistivity decreases with increasing boron concentration, being in the range 0–0.43 eV [24.143]. The energy is 0.35 eV for a boron concentration of 1×10^{18} cm⁻³ and it becomes zero for boron concentrations greater than 1.7×10^{20} cm⁻³ [24.143]. The p-type diamond can also be created by exposing the material to hydrogen plasma. The hydrogenation creates a layer with p-type conductivity with a fairly low resistivity $\approx 10^6$ Ω cm [24.148, 149]. The discovery that both single-crystal and poly-

crystalline diamond can be treated by the plasma has led to successful use of these materials for the fabrication of electronic devices, e.g. the fabrication of FETs.

The growth of n-type diamond is one of the most challenging issues in the diamond field. Many theoretical predictions as well as experimental attempts to obtain n-type diamond have recently been published. Unfortunately, all experimental attempts have up to now delivered n-type diamond with low electron densities; this restricts the use of n-type diamond for the fabrication of transistor. Nitrogen is often used to create n-type diamond, but nitrogen-doped diamond is an electrical insulator at room temperature due to the deep level of 1.7 eV of the nitrogen impurity. Nitrogen is thus not a practical dopant atom to use. Phosphorus would be an obvious candidate but it has an impurity level of ≈ 0.59 eV, which is still rather high. Several reports on phosphorus doping have been published reporting activation energies in the range 0.32–0.59 eV [24.143, 150–152]. Reproducible results on phosphorus doping have been reported recently [24.150, 151]. At room temperature a reasonably high electron mobility of $250 \text{ cm}^2/\text{V}$ was measured in the p-doped films [24.150]. Attempts to use other elements for n-type doping have also been made, e.g. sulphur (0.32 eV [24.143, 152, 153]), and lithium (0.16 eV [24.143, 154]). A survey of p-type doping of diamond has been given by Kalish [24.155].

Despite the experimental difficulties in n-type doping several research groups have succeeded to create a well function pn-junction. Koizumi et al. [24.150] created a pn-junction by epitaxial growth using a MPCVD technique to fabricate a phosphorus doped n-type diamond film on a boron doped p-type diamond film, on the [24.112] oriented surface of a diamond single crystal. The substrate contained over 100 ppm boron and exhibited high electrical conductivity. The electrical and optical properties of the junction have been investigated. The pn-junction exhibited clear diode characteristics, where the rectification ratio was over five orders in magnitude and the turn-on voltage was 4–5 V. The temperature dependence of the hole and electron concentrations in doped diamond films has been studied up to 1000 K. At room temperature the carrier mobilities of the boron and the phosphorus doped film were 300 and $60 \text{ cm}^2/\text{V s}$, respectively, and ultraviolet (UV) light emission has been observed at 235 nm.

A pn-junction has also been formed by using boron-doped p-type and nitrogen-doped n-type diamond films [24.156]. The active diamond films were grown by an MPCVD technique on heavily boron-doped HTHP

diamond single crystals. The forward and reverse I – V characteristics of the junction were studied as a function of temperature up to 400°C . At room temperature the resistivity of the n-layer is extremely high, $\approx 10 \text{ G}\Omega \text{ cm}$. The activation energy of the pn-junction diode saturation current obtained from these measurements was 3.8 eV. This value is in good agreement with theoretical predictions that assumes that the energy of the nitrogen level 1.7 eV. A pn-diode was also formed from a thick lithium-doped layer grown on a highly boron-doped substrate [24.143]. At room temperature the rectification ratio was $\approx 10^{10}$ for $\pm 10 \text{ V}$, but the series resistance was very high $\approx 200 \text{ k}\Omega$, whereas at higher temperatures the series resistance decreased to $30 \text{ k}\Omega$ but the rectification ratio decreased to $\approx 10^6$.

A single-crystal diamond pnp-type BJT consisting of boron/nitrogen pn-junctions has been fabricated [24.147, 156]. The transistor characteristics for common-base and common-emitter configurations have been measured. The temperature-activated leakage current limited the operation of the transistor up to 200°C . The study showed that it was possible to fabricate a pnp-type BJT, but the high resistance of the base $\approx 10 \text{ G}\Omega \text{ m}$ at 20°C limited the operation of the BJTs to the DC mode, small currents (nA), and moderate temperatures.

Diodes as electronic devices must have a high reverse voltage and a low resistance in the forward direction. It has been shown that lightly boron-doped (10^{17} cm^{-3}) Schottky diodes on oxygen-terminated surfaces exhibit good performance at high temperatures. Stable contacts at high temperatures have been developed to create diodes that may operate up to 1000°C [24.157–159]. The diodes showed breakdown behavior at reverse bias, but the reverse current was higher than theoretical values. The breakdown electric field for CVD diamond has been estimated to be 2.106 V/cm [24.143], a value well below that of natural diamond.

FETs

While the development of the diamond bipolar junction transistor is hindered by the lack of n-type diamond with high electron densities, there has been some promising results towards the development of diamond field-effect transistors, although studies at high temperatures are absent. Nevertheless, a short review of the present situation regarding diamond FETs is given here. There are presently two concepts for obtaining high-performance devices: boron δ -doped p-channel FETs and hydrogen-induced p-type surface-channel FET. Since a shallow diamond dopant is absent, δ -doping and

two-dimensional (2D) conduction are essential parts of the diamond device concept.

Hydrogenated surfaces of natural diamond and films grown by plasma-assisted chemical vapor deposition technique exhibit substantial conductivity. Hydrogenation is carried out by treating the diamond surface with hydrogen plasma and cooling to room temperature in hydrogen ambient. The hydrogen-terminated surfaces exhibits the following, a p-type conductivity (2D conduction) of the order of 10^{-4} – $10^{-5} \Omega^{-1}$, a shallow acceptor level which is less than 50 meV, a high carrier concentration 10^{13} cm^{-2} , and a hole mobility in the range 100–150 cm^2/Vs [24.148, 149, 161–165]. The thickness of the conductive layer is estimated to be less than 10 nm. It has been suggested that the surface conductivity depends on the details of the hydrogen termination together with the coverage of physisorbed adsorbates [24.166–168]. The high conductivity of the layer can be destroyed by dehydrogenation of the surface, by exposing the surface to oxygen or by heating in air at a temperature above 200 °C [24.148, 169]. The latter consideration may complicate the fabrication of devices. In order to exploit the conducting layer for the fabrication of high-temperature diamond devices, a way of protecting the layer has to be developed [24.169]. The opposite of hydrogenation is obtained by treating the diamond surface with oxygen plasma. The oxygen-terminated surface becomes highly insulating due to the surface potential pinning at $\approx 1.7 \text{ eV}$ above the valence band [24.170]. This effect is exploited to isolate parts of a device when fabricating devices using the planar process. The hydrogen-terminated areas are transformed into oxygen-terminated ones. The hydrogen-terminated surface has a low surface-state density thus the barrier height between a metal and the surface is almost determined by the work function of the metal only. Usually Al and Au are used as ohmic contacts. Furthermore, when hydrogenation is used to create surface p-type conductivity, alternative cheaper types of diamond can be used [24.171].

The high hole conductivity allows for the fabrication of high-performance FETs, e.g. [24.160, 162, 172–175]. Two types of FET have been investigated, the metal–insulator–semiconductor field-effect transistor (MISFET) and the metal–semiconductor field-effect transistor (MESFET). The high-frequency performance and DC output characteristics of a MISFET with a 0.7- μm gate length has been investigated at room temperature [24.175]. The measurements show that the cutoff frequency f_T and the maximum frequency (MAG – maximum available gain) f_{max} are 11 and

18 GHz, respectively. In addition, a transconductance, g_m , of 100 mS/mm, has been obtained from DC measurements. The DC output characteristics of a circular FET with a gate length of 3 μm has been investigated at room temperature [24.176]. The maximum current was 90 mA/mm at a gate bias -6 V , and the maximum transconductance was 25 mS/mm. Breakdown voltage at pinch-off was -200 V . The high-frequency performance of MESFETs has also been also investigated at room temperature [24.177]. The cutoff frequency and the maximum frequency for a transistor with a 2- μm gate length were 2.2 and 7.0 GHz, respectively. The highest frequencies at room temperature were obtained for a MESFET with a gate length of 0.2 μm [24.174, 178, 179], and the following values were reported: maximum drain current, I_{Dmax} , 360 mA/mm, the transconductance, g_m , 150 mS/mm, the maximum drain voltage, V_{DSmax} , 68 V, and the maximum estimated power capability, P_{Rfmax} , 3.0 W/mm for class A.

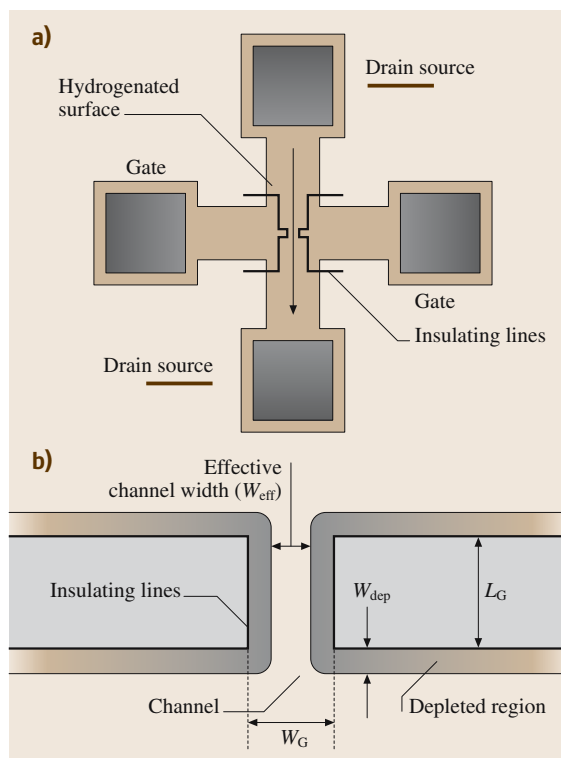

Fig. 24.8 (a) Schema of an in-plane transistor fabricated on a H-terminated diamond surface, using oxidized lines to define channel and gate, (b) channel region with oxidized lines and depletion regions along the lines. L_G and W_G are the gate length and gate width, respectively. (After [24.160])

The cutoff and maximum frequencies were measured to be 11.7 GHz and 31.7 GHz, respectively [24.178]. In a later investigation even higher frequencies were obtained, 21 GHz and 63 GHz, respectively [24.179]. These results indicate that a high gain can be obtained and that this transistor can operate at RF frequencies. Unfortunately, the instabilities of the hydrogen-terminated surface prevented large signal measurements on the device. The structure of a FET fabricated using the hydrogen layer is shown in Fig. 24.8.

The hole concentration of homoepitaxially prepared diamond films was measured for temperatures up to 500 °C. By altering the manner in which the temperature is increased and decreased, it has been shown

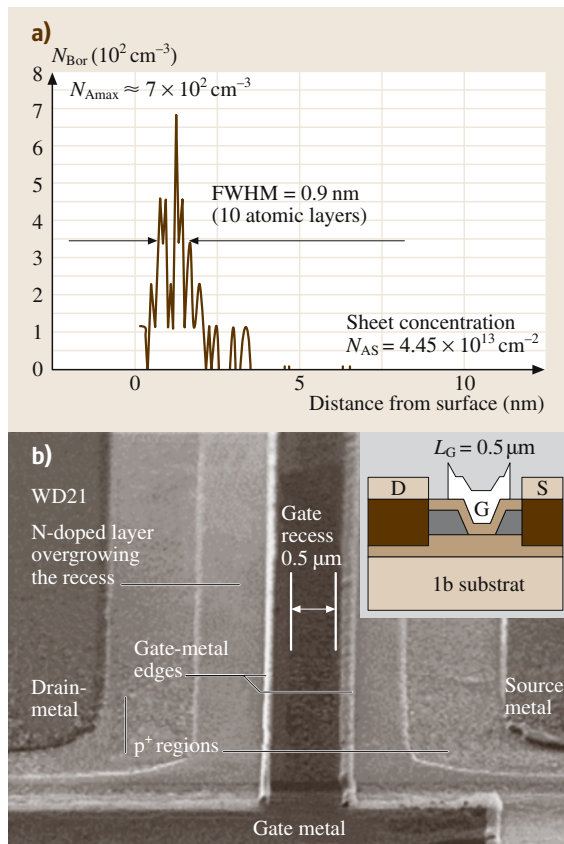

Fig. 24.9 (a) Elastic recoil detection (ERD) analysis of a δ -doped layer showing a full-width at half-maximum (FWHM) of 0.9 nm (10 atomic layers); (b) fabricated recessed gate δ -channel JFET with roughness visible at the bottom of the epitaxially overgrown recess trench. The gate length of 0.5 μm is given by the width of the gate recess. (After [24.174])

that adsorbates from the environment can change the hole concentration in the conducting layer. Furthermore, the influence of the crystalline and surface properties of diamond homoepitaxial layers on device properties of hydrogen-terminated surface-channel FETs has been investigated [24.180].

The δ -channel FET approach is based on boron δ -doping, where the doping profile with peak concentration of 10^{20} cm^{-3} must be confined to within a few nanometers [24.181,182]. The DC output characteristics of δ -doped MESFETs were investigated at room temperature and at 350 °C [24.183]. The maximum drain current I_{Dmax} at room temperature and 350 °C were 35 $\mu\text{A}/\text{mm}$ and 5 mA/mm, respectively. The maximum usable drain-source voltage V_{DSmax} at room temperature and 350 °C were 100 V and 70 V, respectively. A δ -channel JFET, with a δ -doping profile width of 1 nm, has been fabricated and the DC output performance has been investigated at a temperature of 250 °C and −125 °C [24.174]. The mobility of such δ -doped channels would be $\approx 350 \text{ cm}^2/\text{V s}$. At temperature 250 °C all the carriers are activated and a maximum drain current I_{Dmax} of 120 mA/mm has been measured for a transistor with a gate length of 2 μm and a gate width of 100 μm . Figure 24.9 shows δ -doping profile and fabricated recessed gate δ -channel JFET.

All FETs were fabricated from homoepitaxial films deposited on HTHP single-crystal diamond substrates, since the use of polycrystalline diamond films significantly reduced the FETs' performance. In addition, encouraging results which can be regarded as an important breakthrough in the development of high-power diamond electronics on the wafer scale, have been reported recently. The fabrication of high-performance p-type surface-channel MESFETs with sub-micron gate length from a heteroepitaxially grown diamond film. The diamond film was grown on a SrTiO_3 ceramic substrate with an intermediate iridium buffer layer [24.92]. The components exhibited similar performance as structures fabricated from homoepitaxial diamond films. The devices have been analyzed at room temperature under DC, small signal and large-signal RF power conditions. For devices with the smallest gate length of 0.24 μm the following values were obtained, $I_{\text{Dmax}} \approx 250 \text{ mA}/\text{mm}$, transconductance $\approx 97 \text{ mS}/\text{mm}$ and $V_{\text{Dmax}} = 90 \text{ V}$. The cutoff f_T and maximum frequencies $f_{\text{max(MAG)}}$ were measured to be 9.6 and 16.3 GHz, respectively.

In connection with the solid-state diamond FETs, the diamond vacuum field-effect transistor (VFET) ought to be mentioned. This component is part of vacuum electronics using diamond electrodes [24.184]. The diamond

Fig. 24.10 Scanning electron microscopy (SEM) picture of a 2×2 array of gated diamond emitters. (After [24.185])

field emitter has been integrated with silicon-based micro-electromechanical system processing technology in order to obtain a monolithic diamond field-emitter triode on a Si wafer [24.185] (see Fig. 24.10). The monolithic VFET with a self-aligned n^{++} gate has been operated in a vacuum in the triode configuration, with an external anode placed $50\text{ }\mu\text{m}$ above the gate. The low turn-on gate voltage of 10 V, the high anode emission current of $4\text{ }\mu\text{A}$ at an applied gate voltage of 20 V, and the high gain factor of 250, indicate that high-speed diamond VFETs for low and high power can be realized.

Passive Components

Highly oriented heteroepitaxial diamond films grown on wafer-size Si, HOD films, are polycrystalline and cannot therefore be used for the fabrication of transistors or as substrates for the homoepitaxial growth of diamond. Nevertheless, these films possess properties that approach the properties of ideal diamond, and may be the most suitable material for MEMS technologies, heavy-duty, high-frequency and high-temperature electronic components for integrated high-power microwave circuits, and passive components like e.g. capacitors, switches, and planar waveguides. This should also enable the integration with Si- and 3C-SiC electronics.

In connection with high-temperature devices two passive components can be mentioned here, capacitors [24.187] and switches [24.188]. The capacitor has been realized using a diamond membrane as the dielectric and Au as the contacts. The diamond films were grown on large-area Si substrate by the MPCVD technique. The dielectric loss of the capacitor has been measured up to 600°C and the C - V characteristics for

up to 500°C . The capacitor functioned up to 450°C with low loss and constant capacitance, whereas for higher temperatures the capacitance was temperature-dependent. The micro-switch was fabricated using the same type of diamond. The properties of diamond make it an ideal material for switch fabrication. Switches often operate in a vacuum at temperatures around 650°C in a kHz frequency range. Moreover, no change in the switching threshold voltage indicates that there has been no change in the device's mechanical properties.

Heat-Spreading Elements

The properties of diamond suggest that its main application will be in power electronics at high frequencies and high temperature. Natural diamond has the highest known thermal conductivity, 2200 W/mK at room temperature. The highest-quality synthetic diamond grown by CVD technique has an identical thermal conductivity. This implies that power devices can be built on an integrated heat spreader. The high thermal conductivity and thermal stability of diamond will allow ideal heat sinks to be combined with high-power microelectronic and optoelectronic devices operating at high temperatures. Although the thermal conductivity of CVD diamond reduces with decreasing layer thickness, it still exceeds the conductivity of gold, even when the thickness is as low as $2\text{ }\mu\text{m}$ [24.189, 190].

GaN-based FETs have, owing to their excellent characteristics, great potential for high-frequency power

Fig. 24.11 The measured integrated absorption between 2760 and 3030 cm^{-1} plotted against the thermal conductivity determined using the laser flash technique. Samples S1–S3 are marked, the other data points are measured from a range of material with as-grown thickness of 100 – $800\text{ }\mu\text{m}$. (After [24.186])

amplifiers [24.21]. A limitation of the performance of GaN FETs is the rise in operating temperature caused by heat dissipation, which leads to large leakage currents and reduced channel mobility [24.191, 192]. It has been demonstrated that a heat-spreading diamond film can be deposited on GaN FETs, without any degradation of the transistors characteristics [24.190]. The films of thickness 0.7 and 2 μm were deposited by the CVD technique using a new seeding process at low temperatures (less than 500 °C). The GaN FETs were fabricated by a standard process for GaN transistors.

A correlation between the integrated absorption in the IR range of 2700–3030 cm^{-1} , associated with stretch modes of CH_4 , and the measured thermal conductivity at 300 K were reported for CVD diamond samples of different optical quality [24.186]. This provides a quick and reliable method of ascertaining a film's thermal quality. The measured integrated absorption as a function of the thermal conductivity is shown in Fig. 24.11.

Field Emission

The emission of electrons from an electrically active surface by means of tunneling into vacuum is commonly referred to as field emission. The emission properties of diamond, diamond-like carbon (DLC) and carbon-based materials are very robust [24.184]. Thin diamond film deposited by the CVD technique is an excellent cold electron emitter. The electron density yield is around 1 mA/cm^2 for an applied field of 10–100 $\text{V}/\mu\text{m}$. There is much scientific and technological interest in electron field emission from carbon-based materials for applications in many fields, e.g. vacuum field-effect transistors, diodes and triodes, ion sources, electron guns, flat-panel displays, scanning microscopes, energy conversion, and many others. A very large number of reports concerning the field emission from carbon-based materials has been published since the first reported electron emission from diamond in 1991 [24.193]. The physical reason behind the outstanding emission properties of these materials however is still under discussion [24.194].

Depending on the surface termination, diamond can exhibit a low or even negative electron affinity (NEA) [24.165]. The surfaces of diamond and DLC prepared by the CVD technique are naturally terminated by physisorbed hydrogen, making diamond the only semiconductor for which a true negative electron affinity can be obtained. This means that the vacuum level can be below the conduction-band minimum at the surface barrier [24.165]. The hydrogen layer lowers the electron affinity and reduces the turn-on voltage re-

quired to achieve field emission. Many reports treating different aspects of the field-emission process has been published to date, e.g. [24.195–197]. However, there are several problems connected with a direct application of diamond, DLC or other forms of carbon emitters, for instance nonuniform emitter microstructures that result in inconsistent emission and poor long-term stability. In diamond there are no free electrons to be easily emitted. A three-step emission model was proposed by Cutler et al. [24.198]. According to this model the electrons are injected through the back contact, transported through the diamond, and emitted at the diamond–vacuum surface. This model was extended by a proposition [24.199] that: (i) electrons are transferred by the applied electric field from the substrate to the nitrogenated DLC conduction band through a band-to-band tunneling process; (ii) electrons are transported across the nitrogenated DLC film through its conduction band, and (iii) electrons are emitted into the vacuum at the surface of nitrogenated DLC film by tunneling through the barrier. The barrier was crated by the strong upward band-bending at the surface.

Hydrogen has been the most commonly used element for inducing NEA on diamond surfaces. It has been reported that other materials e.g. a Ti layer, can also induce NEA on diamond surfaces [24.200]. High-temperature thermionic electron emission has been studied for several decades [24.201]. Fowler–Nordheim theory, the theoretical foundation of field emission, neglects the effects of temperature on emission characteristics. The temperature dependence of field emission from diamond film surfaces has been reported recently. The electron emission properties of nitrogen-doped diamond films were studied as a function of temperature for up to 950 °C [24.202]. The films were prepared by a microwave-assisted CVD technique for application as a low-temperature thermionic field-emission cathode. The film surfaces were terminated with hydrogen or titanium. Measurements at elevated temperatures showed the importance of a stable surface passivation. Hydrogen-passivated films showed enhanced electron emission, but measurements at elevated temperatures, e.g. 725 °C, showed that the hydrogen layer had degraded rapidly. The titanium-terminated films showed a similar enhanced emission as the hydrogen-terminated ones but the titanium-passivated surfaces were stable up to 950 °C. The electron emission increased with increasing temperature, implying that the field emission is strongly temperature-dependent. At temperatures below 500 °C no emission was detected, while increasing the temperature above 700 °C a strong contribution to

the electron emission was detected. At constant temperature the emission current was nearly constant at low anode voltages, whereas it increased exponentially for anode voltages above 15 kV. At low anode voltages, below 10 kV, the activation energy was approximately 1 eV. This energy value indicates contributions from nitrogen donor levels and defect states to the emission current. It was suggested, according to the emission characteristics, that the emission at low anode voltages could be attributed to thermionic emission of electrons in the diamond's conduction band, whereas the exponential increase at higher voltages indicated a tunneling through or thermionic emission over the potential barrier.

The temperature dependence of electron field-emission characteristics of nitrogen-doped polycrystalline diamond films has also been investigated by [24.203]. The films were grown by the PECVD technique for high-temperature applications. The measurements show that maximum current density increased and the turn-on voltage decreased for temperatures between 300 and 500 °C. The experimental results were interpreted in terms of the Fowler–Nordheim theory and by means of an alternative model that included size and temperature effects explicitly. Furthermore, analysis of the temperature dependence of emission was carried through by parameter estimation of the effective emitting area, field-enhancement factor, and work function. All of the estimates indicated that the emission characteristics exhibit a strong dependence on temperature. From these results it was suggested that the thermally excited electrons are responsible for improved emission at high temperature.

Resistors

An attractive feature of diamond films is their ability to be an excellent dielectric when undoped, or as an interesting resistors when doped. Even polycrystalline or nanocrystalline diamond films, depending on

the process deposition conditions, exhibit breakdown strength (as a dielectric) and power-density capability (as a resistor) with values particularly interesting for high-temperature and high-power applications. Diamond resistors were fabricated on a ceramic substrate of aluminum nitride [24.204], by etching in oxygen plasma from the CVD-deposited layer of boron-doped diamond films. The resistors were intended for investigation of high-power-density characteristics of boron-doped diamond. The resistor exhibits ohmic behavior at low to medium current levels, e.g. up to ≈ 3 mA. At higher currents, thermal excitations are important, and the carrier-density enhancement and conductivity increases. The component enters a thermal runaway situation, but unlike conventional devices, the resistor by virtue of diamonds tolerance for high power, continues to operate at very-high-power and temperature conditions. Operating the resistor under load at high voltages is not unlike operating certain devices in the reverse breakdown mode, except for the much higher power-density levels. For example, the resistance at low power is typically 315 k Ω . The power density just before entering the thermal runaway region is 480 kW/cm². At a maximum current of 14.2 mA and voltage of 413.2 V the resistance fell to 29 k Ω . At the end of the test the power was 5.87 W and the current density was 4730 A/cm² [24.204].

Technological applications of micro-electromechanical systems (MEMs) and optoelectronic system can be broadened by the existence of thermally stable thin-film resistive microheaters. Thermally stable resistors working in a wide temperature range were presented recently [24.205]. Metal containing amorphous carbon like diamond (DLC) films, CrSiDLC and MoSiDLC, were prepared by the CVD technique and doping with Mo and Cr. The resistors, in the form of strips, were deposited on glass ceramic substrates. The films were studied at 700–800 °C. The average resistivity was $2 \times 10^{-3} \Omega$. The thermal coefficient of resistance was $7 \times 10^{-4} \Omega/K$ and the activation energy was 30 meV.

24.3 Summary

This chapter reviewed the advances in research and technology of the wide-band-gap semiconducting material SiC and diamond for high-temperature electronics. The hexagonal 4H-SiC structure is the most appealing for high-temperature power electronics. Basic SiC devices for use in power electronics that can operate at elevated temperature were presented. Four major de-

vice concepts: Schottky and pn-diode, high-frequency devices, power switching devices and high-current devices were discussed. PiN high-blocking-voltage power diodes can operate above 300 °C with an order of magnitude increase in the reverse leakage-current density. JFET is supposed to be the most promising power device. Transistors with blocking voltage up to 5 kV were

characterized up to 300 °C. MOSFETs are still under development, and their operation has been tested up to 400 °C. The operation of high-frequency transistors are limited by to Schottky barrier height and possible applications may be limited to below 350 °C. The most probable near-future devices are thyristors and GTOs since their junctions can withstand higher temperatures, and exhibit large blocking voltages and high conduction currents.

Concerning high-temperature/high-power electronics, diamond has the best properties and is at different stage of research than SiC, since the technology of diamond electronic devices is in its infancy. The foremost progress in diamond research has been in the preparation of high-quality heteroepitaxial diamond, which is the prerequisite for wafer-scale fabrication.

The state of the art concerning high-temperature devices are pn-diodes and Schottky diodes that operate up to 400 °C and 1000 °C, respectively, and passive com-

ponent capacitors and switches that operate up to 450 and 650 °C, respectively. Moreover, the development of FETs have reached important milestones for both DC and RF modes. The performance of these components, however, are still below standard, and components that can operate at high temperatures and high powers are still far away. The development of the BJT is hindered by the unavailability of n-type diamond with high electron concentrations. The application of diamond for field emission has made a lot of progress, since vacuum FETs have been fabricated and field emission from diamond has been studied at high temperatures. Diamond as a heat sink for high-power electronic devices can soon find wide applications due to the recent progress in the preparation of large-area high-quality diamond films. Carbon-based resistors exhibit excellent thermal stability, and with the continuing progress in the preparation of carbon-based materials, will find increasing application in the fabrication of high-temperature devices.

25. Amorphous Semiconductors: Structure, Optical, and Electrical Properties

This chapter is devoted to a survey of the structural, optical and electrical properties of amorphous semiconductors on the basis of their fundamental understanding. These properties are important for various types of applications using amorphous semiconductors.

First, we review general aspects of the electronic states and defects in amorphous semiconductors, i.e., a-Si:H and related materials, and chalcogenide glasses, and their structural, optical and electrical properties.

Further, we survey the two types of phenomena associated with amorphous structure, i.e., light-induced phenomena, and quantum phenomena associated with nanosized amorphous structure. The former are important from the viewpoint of amorphous-silicon solar cells. The latter phenomena promise novel applications of amorphous semiconductors from the viewpoint of nanotechnology.

Amorphous semiconductors are promising electronic materials for a wide range of applications such as solar cells, thin-film transistors, light sensors, optical memory devices, vidicons, electrophotographic applications, X-ray image sensors, europium-doped optical-fibre amplifications etc, particularly, hydrogenated amorphous silicon (a-Si:H) for solar cells, thin-film transistors, X-ray image sensors, and chalcogenide glasses for optical memory devices including digital video/versatile disk (DVD). In this chapter, we emphasize the basic concepts and general aspects of the electronic properties of amorphous semiconductors such as their electrical and optical properties as well as their struc-

tural properties [25.1–3]. Furthermore, some basic and important results of these properties are described to understand these applications and to consider their further development. Light-induced phenomena in amorphous semiconductors, which have been considered to be associated with amorphous structure, are also described.

Nanosized amorphous structures exhibit quantum effects associated with two-dimensional (quantum well), one-dimensional (quantum wire) and zero-dimensional (quantum dot) structures, so they have received significant attention on both the fundamental and application sides. These topics are briefly described.

25.1 Electronic States

Long-range disorder in amorphous network breaks down the periodic arrangement of constituent atoms, as shown in Fig. 25.1. In the figure, the structures of amorphous

and crystalline silicon are shown. The periodic arrangement of atoms makes it easy to treat the electronic states mathematically, i.e., the so-called Bloch the-

Fig. 25.1a,b Structural models of (a) amorphous silicon and (b) crystalline silicon

Fig. 25.2a,b Schematic diagram of the energy levels of atomic orbitals, hybridized orbitals and bands for (a) tetrahedrally bonded semiconductors, e.g., a-Si and for (b) selenium

ory can be applied to crystalline solids. On the other hand, it becomes difficult to treat the electronic states in amorphous solids mathematically. However, electronic states in amorphous semiconductors are simply described in terms of tight-binding approximations and Hartree–Fock calculations. Using these approaches, spatial fluctuations of bond length, bond angle and dihedral angle lead to broadening of the edges of the conduction and valence bands, constructing the band tail. This is due to spatial fluctuations of bond energy between constituent atoms in tetrahedrally coordinated semiconductors such as Si and Ge, in which the bonding state and the antibonding state constitute the valence band and the conduction band, respectively, as shown in Fig. 25.2a. In chalcogenide glasses, the conduction band arises from the antibonding state, while the valence band arises from the nonbonding state, as shown in Fig. 25.2b. The broadening of those bonds also occurs as a result of potential

Fig. 25.3 Schematic diagram of the density of states of the conduction band (delocalized states) and the valence band (delocalized states) shown by the brown-colored. The mobility edge and mobility gap are shown

Fig. 25.4 Schematic illustration of a dangling bond in tetrahedrally bonded amorphous semiconductors

fluctuations associated with the amorphous network of constituent atoms. The static charge fluctuation associated with bond-length and bond-angle variations in the amorphous network has been discussed theoretically [25.4] and experimentally [25.5, 6] in amorphous silicon.

In the band tails, the electronic states have a localized character and their nature changes from localized to delocalized at a critical boundary called the mobility edge, as shown in Fig. 25.3. The energy separation between the two mobility edges of the conduction and valence bands is called the mobility gap. The nature of the conduction and valence bands has been elucidated by means of photoemission spectroscopy [25.7]. The structure of actual samples of amorphous semiconduc-

Fig. 25.5 Schematic illustration of two selenium chains with positively charged threefold-coordinated selenium and negatively charged onefold-coordinated selenium

tors deviates from the ideal random network, namely, coordination of constituent atoms deviates from the normal coordination following the $8 - N$ rule [25.1], where N designates the number of valence electrons. For instance, the normal coordinations of Si and Se are four and two, respectively. However, in actual samples Si atoms with a threefold coordination are present in a-Si (Fig. 25.4), and Se atoms with onefold and threefold coordinations are present in a-Se (Fig. 25.5). These atoms are generally called structural defects (gap states) whose electronic energy levels are located within the band-gap region. In the case of chalcogenide glasses, onefold- and threefold-coordinated Se atoms are called valence-alternation pairs (VAP) [25.8]. The detailed properties of structural defects have been elucidated by means of optical spectroscopies such as photoinduced absorption (PA), photothermal deflection spectroscopy (PDS) and the constant-photocurrent method (CPM), capacitance measurements such as deep-level transient spectroscopy (DLTS) and isothermal capacitance transient spectroscopy (ICTS), and resonance methods such as electron spin resonance (ESR) and electron–nuclear double resonance (ENDOR) [25.2].

In the following, we take a-Si:H as an example and describe the nature of its electronic states. Figure 25.6 shows a schematic diagram of the electronic states involved in the band-gap region of a-Si:H proposed by the authors' group [25.9]. The tails of the

Fig. 25.6 Schematic diagram of the tail and gap states and the recombination processes in a-Si:H. R and NR designate radiative and nonradiative recombination, respectively. A diagram of the density of states spectrum is illustrated on the left-hand side. For the definition of other symbols, see the text. (After [25.9])

conduction and valence bands are expressed by an exponential function with widths of 25 meV [25.10] and 48–51 meV [25.11–13], respectively.

In this figure, the processes of radiative recombination and nonradiative recombination are shown, along with the energy levels of the gap states involved in the recombination processes. The radiative recombination occurs between tail electrons and tail holes at higher temperatures and between tail electrons and self-trapped holes (A centres) at lower temperatures, particularly below 60 K. Such recombinations contribute to the principal luminescence band peaked at 1.3–1.4 eV. These have been elucidated by optically detected magnetic resonance (ODMR) measurements [25.14–16], and are briefly mentioned in Sect. 25.3. The radiative recombination center participating in the low-energy luminescence (defect luminescence) may be attributed to distant $T_3^+ - N_2^-$ pair defects [25.17, 18], in which T_3^+ and N_2^- are the positively charged threefold-coordinated silicon center and the negatively charged twofold-coordinated nitrogen center, respectively. The N_2^- centers are created from contaminating nitrogen atoms introduced during sample preparation. On the other hand, close $T_3^+ - N_2^-$ pair defects act as nonradiative recombination centers. A typical nonradiative recombination center in a-Si:H is the neutral silicon dangling bond, i. e., T_3^0 . The details of the recombination processes in a-Si:H are described in Sect. 25.3.

25.2 Structural Properties

25.2.1 General Aspects

The structural properties of amorphous semiconductors have been investigated by means of X-ray, electron and neutron diffraction, transmission electron microscope (TEM) and scanning electron microscope (SEM), extended X-ray absorption fine structure (EXAFS), small-angle X-ray scattering (SAXS), Raman scattering, infrared absorption (IR) and nuclear magnetic resonance (NMR). The absence of long-range order in amorphous semiconductors is manifested in diffraction techniques, e.g., electron diffraction for a-Si results in a halo pattern as shown in Fig. 25.7a, while Laue spots are seen for c-Si, as shown in Fig. 25.7b. The medium-range order of 0.5–50 nm has been discussed based on SAXS measurements.

25.2.2 a-Si:H and Related Materials

The radial distribution function (RDF) in a-Si has been obtained from an analysis of curves of scattered electron intensity versus scattering angle from electron diffraction measurements, as shown in Fig. 25.8 [25.19]. From a comparison of RDF curves of a-Si and c-Si, it was concluded that the first peak of a-Si coincides with that of c-Si, the second peak of a-Si is broadened compared to that of c-Si, the third peak of c-Si almost disappears and a small peak appears, shifted from the third peak of c-Si, as shown in Fig. 25.8. These results indicate that the bond length of a-Si is elongated by 1% over that of c-Si ($= 2.35 \text{ \AA}$), and that the bond angle is tetrahedral ($= 109.47^\circ$) with a variation of 10% from that of c-Si. Using the neutron diffraction technique, the RDF was also deduced from the measured structure factor, $S(Q)$, as a function of Q (the momentum transfer) in a-Si [25.20]. The RDF curve of a-Si exhibiting these features was well simulated by

the continuous random network model [25.21]. Since then, computer-generated models have been constructed (see, e.g., Kugler et al. [25.20]), using the Monte Carlo (MC) method [25.22], the molecular dynamics (MD) method [25.23] and the reverse MC method [25.24, 25]. Here, the reverse MC method, i.e., a MC simulation repeatedly carried out to reach consistency with the measured RDF curve and curve of structure factor $S(Q)$ versus Q from the neutron diffraction data, is briefly mentioned. First we start with an initial set of Cartesian coordinates (particle configuration) and calculate its RDF and $S(Q)$. Comparing the calculated RDF and $S(Q)$ with the measured ones, the new particle configuration is generated by random motion of a particle, being consistent with the constraint, e.g., the coordination number. From the reverse MC simulation, the bond-angle distribution is derived, i.e., it shows a peak at the tetrahedral angle, 109.5° and small peaks at $\approx 60^\circ$ and $\approx 90^\circ$ [25.26].

In a-Si:H, knowledge of the hydrogen configuration is important to understand its electronic properties. This is obtained by NMR [25.27, 28] and IR measurements [25.29]. The bonding modes of Si and H atoms are Si–H, Si–H₂, (Si–H₂)_n and Si–H₃ bonds. The concentrations of these hydrogen configurations depend on the preparation conditions, particularly on the substrate temperature, i.e., the deposition temperature. a-Si:H films prepared at 250 °C mostly contain Si–H bonds in incorporated hydrogen (hydrogen content of $\approx 10 \text{ at. \%}$), while those prepared at lower temperatures such as room temperature contain all these bonds in incorporated hydrogen (hydrogen content of

≈ 30 at. %). The hydrogen configuration has also been investigated by neutron scattering measurements using the isotope-substitution method [25.30,31]. Partial pair-correlation functions of Si–Si, Si–H and H–H are

obtained from those measurements. The Si–H bond length is 1.48 Å.

Raman scattering measurements provide useful information about microcrystallinity, i.e., the volume fraction of the amorphous phase in microcrystalline silicon [25.33]. The Raman shift associated with transverse optical (TO) phonons is observed at 520 cm^{-1} for c-Si, while it is observed at 480 cm^{-1} for a-Si.

25.2.3 Chalcogenide Glasses

The chalcogenide glasses are composed of chalcogenide atoms and other constituent atoms such as As, Ge etc. Their crystalline counterpart has a structure consisting of threefold-coordinated As atoms and twofold-coordinated chalcogens, i.e., c-Se and c-As₂S₃ exhibit a chain structure and a layered structure, respectively. The structure of the chalcogenide glasses is fundamentally built from these constituent atoms, keeping their coordination in the crystalline counterpart. However, actual glasses contain wrong bonds, i.e., homopolar bonds such as Se–Se, As–As, Ge–Ge etc. In the following, we take two examples of chalcogenide glasses, As₂X₃ ($X = \text{S, Se}$) and GeX₂ ($X = \text{S, Se}$).

1. As₂X₃ ($X = \text{S, Se}$)

This type of glass, e.g., As₂S₃, is mainly composed of AsS₃ pyramid units, i.e., a random network of these units sharing the twofold-coordinated S site [25.34]. There is no correlation between As atoms, but interlayer correlation seems to hold even for the amorphous structure.

2. GeX₂ ($X = \text{S, Se}$)

Silica glass (SiO₂) is a well-known material, which is mainly composed of SiO₄ tetrahedron units sharing the twofold-coordinated O site (the summit-sharing structure. See Fig. 25.9a). On the other hand, SiS₂ and GeSe₂ glasses have a different structure from SiO₂ glass: the tetrahedron units are connected through two X sites (the edge-sharing structure) along with one X site (the summit-sharing structure. See Fig. 25.9b). For example, in GeSe₂, the edge-sharing structure occurs at a level of more than 30% and the summit-sharing structure with less than 70%. Actually, wrong bonds (homopolar bonds) Ge–Ge, Se–Se exist in GeSe₂ glass. A structural model of GeS₂ [25.32] is shown in Fig. 25.10.

25.3 Optical Properties

25.3.1 General Aspects

Optical absorption and luminescence occur by transition of electrons and holes between electronic states such as conduction and valence bands, tail states, and gap states. In some cases, electron–phonon coupling is strong and, as a result, self-trapping occurs. Exciton formation has also been suggested in some amorphous semiconductors.

The absorption of photons due to interband transition, which occurs in crystalline semiconductors, is also observed in amorphous semiconductors. However, the absorption edge is not clear since interband absorption near the band gap is difficult to distinguish from tail absorption in the absorption spectra. Figure 25.11 schematically illustrates typical absorption spectra of amorphous semiconductors. The absorption coefficient, α , due to interband transition near the band gap is known to be well described by the following equation [25.35]

$$\alpha \hbar\omega = B(\hbar\omega - E_g)^2, \quad (25.1)$$

where $\hbar\omega$ and E_g denote the photon energy and optical gap, respectively. In most amorphous semiconductors, the optical gap E_g is determined by a plot of $(\alpha \hbar\omega)^{1/2}$ versus $\hbar\omega$, which is known as Tauc's plot. The photon energy at which the absorption coefficient is 10^4 cm^{-1} , E_{04} , is also used for the band gap in a-Si:H. The absorption coefficient at the photon energy just below the optical gap (tail absorption) depends exponentially on the photon energy, $E = \hbar\omega$, as expressed by

$$\alpha(E) \propto \exp\left(\frac{E}{E_U}\right), \quad (25.2)$$

where E_U is called the Urbach energy and also the Urbach tail width. In addition, optical absorption by defects appears at energies lower than the optical gap.

Photoluminescence (PL) occurs as a result of the transition of electrons and holes from excited states to the ground state. After interband excitation, electrons relax to the bottom of the conduction band by emitting phonons much more quickly than the radiative transition. Similarly, the holes also relax to the top of the valence band. In the case of crystalline semiconductors without defects or impurities, there is no localized state in the band gap and PL occurs by transition between the bottom of the conduction band and the top of the valence band. In this case the k -selection rule, $k_{\text{photon}} = k_i - k_f$, must be satisfied, where k_{photon} , k_i and k_f denote the wavenumbers of photons, and elec-

trons in the initial and final states, respectively. Since k_{photon} is much smaller than k_i and k_f , we can rewrite the selection rule as $k_i = k_f$. Semiconductors satisfying this condition are called direct-gap semiconductors. Crystalline silicon is one semiconductor in which the direct transition is not allowed by the k -selection rule (indirect-gap semiconductors), but the transition is allowed by either absorption of phonons or their emission. On the other hand, strong PL is observed in a-Si:H. In amorphous semiconductors, the k -selection rule is relaxed and, furthermore, the electrons and holes relax to localized states in the gap before radiative recombination. Thus, PL occurs by transitions between localized states.

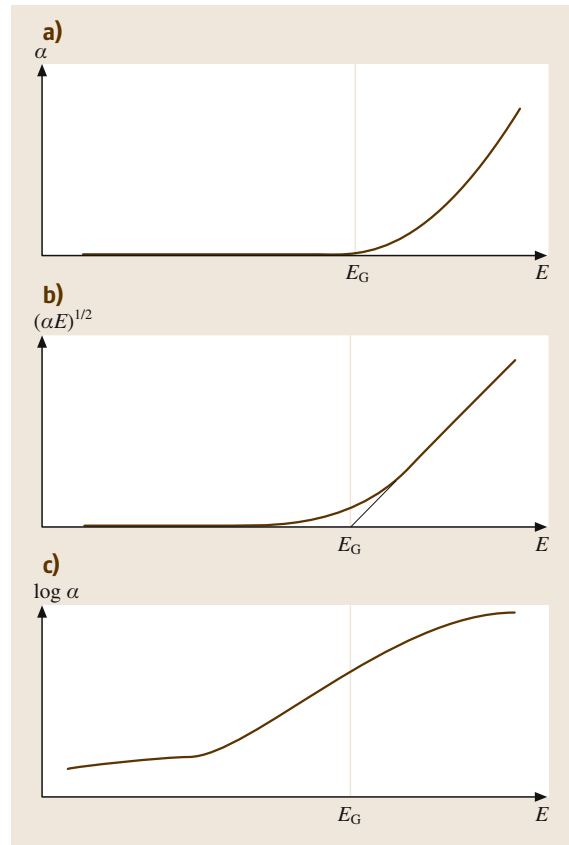

Fig. 25.11a–c Schematic illustration of the absorption spectra of amorphous semiconductors. **(a)** The absorption coefficient α plotted as a function of photon energy E . **(b)** $(\alpha E)^{1/2}$ versus E (Tauc's plot). **(c)** $\log \alpha$ versus E . E_G is the optical gap determined from (b)

The lifetime measurement is important for the identification of the origin of the PL since the PL spectra in most amorphous semiconductors are featureless and do not provide much information. The probability of radiative transition between localized electrons and holes depends exponentially on their separation, R . The lifetime is estimated by $\tau = \tau_0 \exp(2R/R_0)$ where R_0 denotes the radius of the most extended wavefunction [25.36]. When the Coulomb interaction is strong enough, excitons are formed. Exciton formation is also suggested in some amorphous semiconductors. The total spin of excitons, S , is either 0 or 1. Singlet excitons of $S = 0$ have a lifetime in the nanosecond region, while triplet excitons with $S = 1$ have a lifetime much longer than that of singlet excitons, e.g. $\tau = 1$ ms, since the transition is forbidden by the spin selection rule.

PL measurements combined with magnetic resonance are a powerful means to study recombination processes [25.14, 15]. This is called optically detected magnetic resonance (ODMR) measurements. PL from triplet excitons has been suggested from ODMR measurements, as described in Sects. 25.3.2 and 25.3.3.

The photoconductivity measurements provide us with useful information about the processes of carrier transport and recombination. Their results on a-Si:H and chalcogenide glasses are briefly reviewed in Sects. 25.3.2 and 25.3.3, respectively.

T_s : Deposition temperature, [H]: Hydrogen content

25.3.2 a-Si:H and Related Materials

The band gap of a-Si:H determined from Tauc's plot is 1.7–1.9 eV, depending on the preparation condition, particularly the deposition temperature, T_s , i.e. hydrogen content, [H], [25.37–39, 48] as shown in Table 25.1. The absorption coefficient of visible light for a-Si:H is of the order 10^5 – 10^6 cm⁻¹, which is large compared to that of crystalline silicon. A thickness of 1 μ m is enough to absorb visible light. Thus a-Si:H is suitable for application to solar cells especially when a thin film is desired.

The optical gap, E_g , and the Urbach tail width, E_U , of a-Si:H, a-Ge:H and Si-based alloys are shown in Table 25.2. Some a-Si:H-based alloys such as a-Si_{1-x}N_x:H and a-Si_{1-x}C_x:H have a band gap wider than that of a-Si:H depending on the composition, x . In the preparation of these alloys, x can be varied continuously over a certain range. Thus, the band gap can be varied arbitrarily. It is possible to prepare multilayer films consisting of layers with different band gaps, such as a-Si:H/a-Si_{1-x}N_x:H. Quantum size effects in multilayer films will be described in Sect. 25.6.

It is difficult to obtain the absorption spectra below the band gap from transmittance measurements in a-Si:H, which is normally prepared as a thin film. Such low absorption in a-Si:H has been measured by PDS and CPM.

PL from a-Si:H was observed by Engemann and Fischer [25.49] for the first time. The quantum efficiency has been found to be of the order of unity [25.50], although it decreases with increasing density of dangling bonds [25.51]. PL spectra from a-Si:H films generally consist of two components. The first is observed as a peak at 1.3–1.4 eV with a FWHM of 0.3 eV. The other component, which is called low-energy PL (defect PL), is observed at 0.8–0.9 eV.

The origin of the main peak has not been fully understood. Electrons and holes in the tail states may give

Table 25.2 Band gap energies, Urbach tail widths and dark conductivities at room temperature for a-Si:H, a-Ge:H and related materials

a-Si _{0.74} N _{0.26} :H	≈ 2.0	≈ 100	1.4×10^{-8}	[25.44, 45, 47]

rise to this PL. Dunstan and Boulitrop [25.52] have shown that the PL spectra of a-Si:H can be understood without considering electron–phonon coupling. However, the electron–phonon coupling has still been discussed. Morigaki proposed a model on the basis of ODMR measurements [25.14] in which self-trapped holes and tail electrons are the origin of the PL at low temperatures [25.53], while tail holes and tail electrons participate in the PL at high temperatures.

In the case of radiative recombination of localized electron–hole pairs the lifetime depends exponentially on the separation of the electron and the hole, as described in Sect. 25.3.1. When the spatial distribution of electrons and holes is random, a broad lifetime distribution is predicted. This model describes some properties well, e.g., the generation-rate dependence of the lifetime. However, it has been pointed out that we have to consider the PL from specific electronic states such as excitonic PL to understand the lifetime distribution at low generation rate [25.54–56]. PL due to triplet excitons in a-Si:H has been suggested by optically detected magnetic resonance measurements [25.57, 58]. The PL from singlet excitons, which is expected to have lifetime of about 10 ns, has also been reported [25.59–61].

The low-energy PL is emission from deep gap states created by defects. However the origin of low-energy PL is not neutral dangling bonds (T_3^0) of Si since they act as nonradiative centers, as has been suggested from optically detected magnetic resonance [25.62]. Yamaguchi et al. [25.17, 18] proposed a model in which the origin of the low-energy PL is $T_3^+ - N_2^-$ pairs.

The drift mobility of carriers, i.e., electrons and holes, in a-Si:H has been measured by the method of time of flight (TOF), using blocking electrodes [25.63]. In the measurement, carriers are created by an optical pulse near one of the electrodes and run as a sheet-like shape against another electrode. The transient photocurrent i_p

associated with a pulsed optical excitation exhibits a dispersive behavior, as shown in Fig. 25.12 [25.63, 64], which is given by

$$i_p \propto t^{-(1-\alpha)} \quad \text{for } t < t_r \quad (25.3)$$

and

$$i_p \propto t^{-(1+\alpha)} \quad \text{for } t > t_r, \quad (25.4)$$

where t_r designates the transit time, as shown in Fig. 25.12, given by

$$t_r = \frac{L}{\mu_d F}, \quad (25.5)$$

in which L , μ_d and F are the separation of the two electrodes, the drift mobility and the magnitude of the electric field, respectively. In dispersive conduction, the drift mobility depends on the thickness of the samples. This is due to dispersive carrier processes, which are caused by dispersion of the flight time. Band conduction with multiple trapping of carriers also exhibits dispersive conduction, as was observed in a-Si:H and chalcogenide glasses. For undoped a-Si:H, the drift mobility was on the order of $1 \text{ cm}^2/\text{V}$ at room temperature. $\alpha = 0.51$ was obtained as 160 K [25.11]. This transient behavior depends on temperature, i.e., it becomes more dispersive at lower temperatures. α is related to the exponential tail width (normally equal to E_U) $E_c \equiv k_B T_c$ as follows:

$$\alpha = \frac{T}{T_c}. \quad (25.6)$$

From the value of α , the tail width of the conduction band has been obtained to be 25 meV. For hole transport, dispersive behavior has also been obtained and a drift mobility of the order of $10^{-2} \text{ cm}^2/\text{V}$ has been obtained at room temperature.

For the steady-state photoconductivity of undoped a-Si:H, it has been generally accepted that photoconduction occurs through electrons in the conduction band at temperatures above $\approx 60 \text{ K}$ and through hopping of tail electrons at temperatures below $\approx 60 \text{ K}$. The detailed processes of trapping and recombination of carriers involved in photoconduction have been discussed in many literatures (see, e.g., Morigaki [25.2]; Singh and Shimakawa [25.3]). In relation to this issue, spin-dependent photoconductivity measurements are very useful, and have therefore been extensively performed on a-Si:H [25.65–67].

Fig. 25.12 Schematic illustration of the transient photocurrent curve for the dispersive transport

25.3.3 Chalcogenide Glasses

As mentioned in Sect. 25.3.1, the absorption coefficient for the interband transition in many chalcogenide

glasses is well described by Tauc's relationship (25.1). The optical gap E_g is shown in Table 25.3 for various chalcogenide glasses. The effect of light on optical absorption in chalcogenide glasses is known as photo-darkening. This effect will be briefly reviewed in Sect. 25.5.

PL has been observed in a-Se, arsenic chalcogenide glasses and germanium chalcogenide glasses. PL in chalcogenide glasses is known to have a large Stokes shift. The peak energy in the PL spectra is approximately half of the band gap. This Stokes shift has been attributed to strong electron–phonon coupling [25.71]. The electronic states responsible for the PL have not been well understood. There has been some experimental evidence

for PL from self-trapped excitons. The observation of triplet excitons has been reported in ODMR measurements for chalcogenide glasses such as As₂S₃ and As₂Se₃ [25.72–74].

Dispersive transport was observed in the transient photocurrent for the first time for chalcogenide glasses such as a-As₂Se₃, in which the hole transport dominates over the electron transport [25.63]. The drift mobility of holes ranges between 10^{-3} – 10^{-5} cm²/V, depending on the temperature and electric field. The zero-field hole mobility at room temperature is about 5×10^{-5} cm²/V. The steady-state photoconduction in a-As₂Se₃ has been considered to be governed by charged structural defects such as VAPs.

25.4 Electrical Properties

25.4.1 General Aspects

Electrical Conductivity

Electrical conduction in amorphous semiconductors consists of band conduction and hopping conduction. Band conduction in undoped amorphous semiconductors is characterized by

$$\sigma = \sigma_0 \exp\left(-\frac{E_a}{k_B T}\right), \quad (25.7)$$

where σ and σ_0 are the electrical conductivity and a prefactor, respectively, and E_a , k_B and T are the activation energy, the Boltzmann constant and the temperature, respectively. E_a is given by either $E_c - E_F$ or $E_F - E_V$, depending on whether electrons or holes are considered,

where E_c , E_V and E_F are the mobility edges of the conduction band and the valence band, and the Fermi energy, respectively. Hopping conduction in amorphous semiconductors consists of nearest-neighbor hopping and variable-range hopping [25.1]. Nearest-neighbor hopping is well known in crystalline semiconductors, in which electrons (holes) hop to nearest-neighbor sites by emitting or absorbing phonons. Variable-range hopping is particularly associated with tail states, in which electrons (holes) in tail states hop to the most probable sites. This type of hopping conductivity σ_p is characterized by the following temperature variation:

$$\sigma_p = \sigma_{p0} \exp\left(-\frac{B}{T^{1/4}}\right). \quad (25.8)$$

The Hall Effect

The Hall effect is used for the determination of carrier density and its sign in crystalline semiconductors. For amorphous semiconductors, however, the sign of the Hall coefficient does not always coincide with that of the carriers [25.76]. Such a sign anomaly has been observed in a-Si:H, as will be shown in Sect. 25.4.2.

Thermoelectric Power

The thermoelectric power S associated with band conduction of electrons is given by

$$S = -\frac{k_B}{e} \left(\frac{E_c - E_F}{k_B T} + A \right), \quad (25.9)$$

where A is a quantity depending on the energy dependence of the relaxation times associated with electrical conduction. For hole conduction, S is given by (25.9) except that $E_c - E_F$ is replaced by $E_F - E_V$ and that the sign of S is positive. The sign of S coincides with that of the carriers. The thermoelectric power S (25.9) is related to the electrical conductivity σ (25.7) as follows [25.77]:

$$\ln \sigma + \left| \frac{e}{k_B} S \right| = \ln \sigma_0 + A \equiv Q. \quad (25.10)$$

The temperature-dependent quantity Q is defined as above. The activation energies of σ and S , E_σ and E_S , are equal to each other. Then, Q is defined by Q_0 as follows:

$$Q = \ln \sigma_0 + A \equiv Q_0. \quad (25.11)$$

However, if E_σ is not equal to E_S , Q is generally expressed by

$$Q = Q_0 - \frac{E_Q}{k_B T} \quad (25.12)$$

$$E_Q = E_\sigma - E_S. \quad (25.13)$$

It has been generally observed that E_σ is greater than E_S , i.e., $E_\sigma > E_S$. This has been accounted for in terms of long-range fluctuation of the band edge. The electrical conduction is due to those carriers that are thermally excited into the valley of the band-edge fluctuation and cross over its barrier, while the thermoelectric power, i.e., transport of phonon energy by carriers, is governed by carriers in the valleys. Thus, a relationship of $E_\sigma > E_S$ can be accounted for in terms of long-range fluctuation of the band edge [25.77].

Drift Mobility

The drift mobility of carriers is measured by the TOF method, as mentioned in Sect. 25.3.2. The drift mobility μ_d is estimated from (25.5).

In the following, the electrical properties of a-Si:H and related materials and chalcogenide glasses are described.

25.4.2 a-Si:H and Related Materials

A typical example of band conduction and variable-range hopping conduction is shown in Fig. 25.13, which is the temperature dependence of the electrical conductivity for a-Si_xAu_{1-x} films prepared by vapor evaporation [25.75]. Band conduction occurs at high temperatures and variable-range hopping conduction at low temperatures. The $T^{-1/4}$ law of temperature variation of electrical conductivity is clearly seen in Fig. 25.14. The values of the dark conductivities of a-Si:H, a-Ge:H and related materials at room temperature are shown in Table 25.2. Figure 25.15 shows the temperature dependencies of S for a-Ge:H, in which two slopes of the curve of S versus T^{-1} are seen with 0.43 eV in the high-temperature range and 0.17 eV in the low-temperature range [25.78]. This crossover of two slopes is accounted for in terms of two different mechanisms of electrical conduction, i.e., band conduction at high temperatures and hopping conduction in the band-tail states at low temperatures [25.79]. In amorphous semiconductors, doping control is generally difficult, because the constituent

Fig. 25.13 Temperature dependence of the electrical conductivity for an a-Si_xAu_{1-x} film. (After [25.75])

Fig. 25.14 Electrical conductivity versus $T^{-1/4}$ for $a\text{-Si}_x\text{Au}_{1-x}$ films. (After [25.75])

atoms obey the so called $8 - N$ rule to satisfy the coordination of covalent bonds with their neighboring atoms. In $a\text{-Si:H}$, however, n-type doping and p-type doping were performed by using phosphorus (group V element) and boron (group III element), respectively [25.80].

The Hall coefficient of $a\text{-Si:H}$ has been measured [25.76]. In crystalline semiconductors, when the carriers are electrons, its sign is negative, and when the carriers are holes, its sign is positive. The sign of the Hall coefficient is generally negative irrespective of that of the carriers in amorphous semiconductors. This has been accounted for in terms of the random phase model [25.82]. However, for the Hall coefficient of $a\text{-Si:H}$, this is not the case, i.e., when the carriers are electrons, the sign is positive, and when the carriers are holes, the sign is negative. Such an anomalous Hall coefficient in $a\text{-Si:H}$ is called double reversal of the Hall coefficient and has been accounted for, taking into account antibonding orbitals for electrons and bonding orbitals for holes [25.83].

25.5 Light-Induced Phenomena

Light-induced phenomena in amorphous semiconductors were first observed for chalcogenide glasses

Fig. 25.15 Thermoelectric power versus T^{-1} for various $a\text{-Ge:H}$ films. The solid lines are the calculated results. The insert shows the model on which the calculations are based. Carriers in states just above E_A move in extended states, those at E_A move by hopping. The dotted curve marked B-S was obtained by Beyer and Stuke [25.81] for a slowly evaporated sample annealed at 310 °C [25.78]

25.4.3 Chalcogenide Glasses

The values of the dark conductivities of chalcogenide glasses at room temperature are shown in Table 25.3 along with those of μ_d at room temperature. In chalcogenide glasses, the Fermi level is pinned near the midgap and this has been considered to be due to VAP defects with negative correlation energy. Thus, doping seems difficult, except for a few cases, e.g., the incorporation of Bi into $a\text{-Ge:S}$ and $a\text{-Ge:Se}$ increases the direct current (DC) conductivity by 6–7 orders of magnitude [25.84, 85]. This doping effect is due to chemical modification instead of conventional doping. Furthermore, Cd–In–S chalcogenide glasses exhibit $\sigma \approx 1 \times 10^{-2} \Omega^{-1}\text{cm}^{-1}$ at room temperature [25.70].

as photo-darkening, PL fatigue and photostructural changes associated with illumination whose energy

Fig. 25.16 Optical absorption edge of As_2S_3 films annealed or illuminated with unpolarized or linearly polarized light (α_\perp : solid line and α_\parallel : dashed line). α_\parallel and α_\perp refer to polarization along the plane of illumination and perpendicular to it, respectively. (After [25.87])

equals to or exceeds the band-gap energy (see, e.g., Shimakawa et al. [25.86]; Singh and Shimakawa, [25.3]). Photo-darkening is an effect in which the absorption edge shifts towards lower photon energy under illumination, as shown in Fig. 25.16 [25.87]. PL fatigue is the decrease of the PL intensity associated with illumination. Photostructural changes are observed as changes of the volume (generally expansion) of the sample with illumination. PL fatigue may be due to light-induced creation of charged structural defects acting as nonradiative recombination centers. For the photo-darkening and the photostructural change, it has been discussed whether they are independent of each other or not. Thus, the origins of these phenomena are still unclear.

Light-induced phenomena in a-Si:H were observed first in the dark conductivity and photoconductivity, i.e., drops in their values after prolonged illumination of band-gap light (the so-called Staebler–Wronski effect [25.88]). Subsequently, such phenomena have been observed in PL, optical absorption and ODMR etc. [25.2]. This effect also gives rise to degradation of the performance of amorphous-silicon solar cells, so that this has received great attention from the viewpoint of application. After prolonged illumination, dangling bonds were found to be created [25.89,90], so that light-induced creation of dangling bonds has been considered

Fig. 25.17 (a) Self-trapping of a hole by a weak Si–Si bond adjacent to a Si–H bond. (b) Nonradiative recombination of a self-trapped hole with an electron. (c) A Si–H bond is switched toward the weak Si–Si bond and a dangling bond is left behind. (d) Formation of two separate dangling bonds after hydrogen movements and repeating of processes shown in (a)–(c)

as the origin of these phenomena. Several models have been proposed for mechanisms for light-induced creation of dangling bonds [25.53, 91–96], but this issue is still controversial (see, e.g., Morigaki [25.2]; Singh and Shimakawa [25.3]). Very recently, the creation of a number of dangling bonds such as $1 \times 10^{19} \text{ cm}^{-3}$ after pulsed optical excitation has been observed in high-quality a-Si:H films [25.97, 98]. This result has been accounted for in terms of the authors' model [25.99], based on a combination of the following processes occurring during illumination. Self-trapping of holes in weak Si–Si bonds adjacent to Si–H bonds triggers these weak bonds to break using the phonon energy associated with nonradiative recombination of electrons with those self-trapped holes (Fig. 25.17a and b). After Si–H bond switching and hydrogen movement, two types of dangling bonds are created, i.e., a normal dangling bond and a dangling bond with hydrogen at a nearby site, i.e. so-called hydrogen-related dangling bonds (Fig. 25.17c and d). In the latter, hydrogen is dissociated from the Si–H bond as a result of nonradiative recombination at this dangling bond site. Dissociated hydrogen can terminate two types of dangling bonds (Fig. 25.18c and d) or can be in-

Fig. 25.18 (a) Dissociation of hydrogen from a hydrogen-related dangling bond and insertion of hydrogen into a nearby weak Si—Si bond (formation of a new hydrogen-related dangling bond). (b) Two separate dangling bonds, i. e. a normal dangling bond and a hydrogen-related dangling bond. (c) Dissociation of hydrogen from a hydrogen-related dangling bond and termination of a normal dangling bond by hydrogen. (d) Termination of a hydrogen-related dangling bond by hydrogen

serted into a nearby weak Si—Si bond (Fig. 25.18a). The dependencies of the density of light-induced dangling bonds on illumination time and generation rate have been calculated using the rate equations governing these processes. The results have been compared with experimental results obtained under continuous

illumination and pulsed illumination with good agreement. Light-induced structural changes, i. e., volume change [25.100] and local structural changes around a Si—H bond [25.101] have also been observed in a-Si:H and the origins for these changes have been discussed [25.102–104].

25.6 Nanosized Amorphous Structure

Recent technologies have enabled us to control the properties of semiconductors by introducing artificial structures of nanometer size such as quantum wells, quantum wires and quantum dots. The quantum well is formed by preparing multilayers consisting of two semiconductors. Figure 25.19a illustrates the conduction and valence band edges in such multilayers consisting of two semiconducting materials with different band gaps, plotted as functions of the distance from the substrate, z . The curves of the conduction and valence bands in Fig. 25.19a are considered to be the potentials for the electrons and holes, respectively. The motion of the electrons and holes is assumed to be described by effective mass equations which are similar to the Schrödinger equation. When the barriers of the potentials are high enough to prevent the carriers from moving to the adjacent well, the quantum levels (for motion along the z -axis) are as illustrated in Fig. 25.19a. The band gap

of the multilayer, E_g , is equal to the separation of the quantum levels of the lowest energy in the conduction and valence bands, as shown in Fig. 25.19a. E_g increases with decreasing thickness of the well layer, L_w ; this is well known as the quantum-size effect. When the height of the barrier is infinite, $\Delta E = E_g - E_{gw}$ is proportional to L_w^{-2} , where E_{gw} denotes the band gap of the material of the well layer.

Multilayers of various amorphous semiconductors have been prepared. Observation of the quantum size effect has been reported in some amorphous semiconducting multilayers. For example, the shift of the optical gap of an a-Si:H/a-Si_{1-x}N_x:H multilayer from that of a-Si:H, ΔE , is proportional to L_w^{-2} , where L_w is the thickness of the a-Si:H layers (e.g. Morigaki [25.2]; see Yamaguchi and Morigaki [25.105]; and references therein). The result, $\Delta E \propto L_w^{-2}$, is consistent with quantum size effect in a square-well potential.

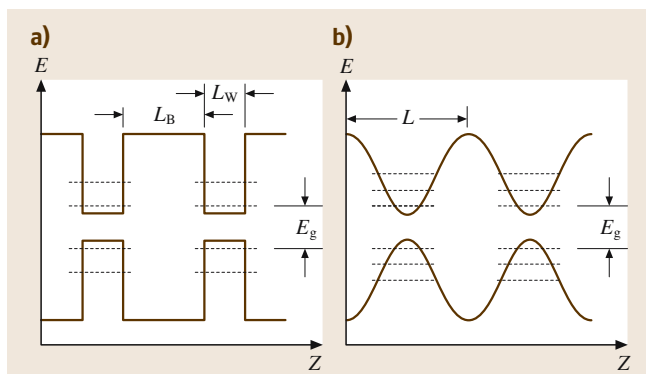

Fig. 25.19a,b The edges of the conduction and valence bands in (a) multilayer films and (b) band-edge modulated films, as functions of z , where z denotes distance from the substrates. The dashed lines indicate quantum levels. The band gap E_g , which increases due to the quantum size effect, is also shown

In the case of amorphous semiconductors, it is easy to introduce a potential well of arbitrary shape, because the optical gap of the amorphous semiconducting alloy, which depends on the composition, can be varied continuously within a certain range. The authors have prepared a new type of a-Si:H-based film called band-edge modulated (BM) a-Si_{1-x}N_x:H, in which the potentials for electrons and holes are sinusoidal functions of z [25.106,107]. The band-edges for the BM films are illustrated in Fig. 25.19b. In this case, the quantum

size effect is also expected, similarly to the case of multilayer films. However, the quantum levels and the size dependencies of the band gap are different from those in the case of multilayer films. In the case of BM, the potential is approximately parabolic at the bottom of the well. In this case the quantum levels have the same separation as that illustrated in Fig. 25.19b. We expect that the shift of the optical gap in BM films, ΔE , will be proportional to L^{-1} , where L denotes the modulation period. The band gap of BM films observed in experiments are in agreement with that expected from the above consideration [25.106]. Parabolic potentials in crystalline semiconductors have also been introduced (see Gossard et al. [25.108]). However it is difficult to obtain such structures that are small enough to observe significant quantum effects in crystalline semiconductors.

Recently, preparation of amorphous silicon quantum dots in silicon nitride has been reported [25.109]. Theoretical calculations for silicon nanostructures [25.110] have predicted that the oscillator strength in low symmetry is larger than that in high symmetry. A large quantum efficiency for PL is expected in the case of amorphous quantum dots. Thus, amorphous quantum wires and dots have potential applications in light-emitting devices with high efficiency.

Chalcogenide glasses multilayers have been prepared [25.111–113], whose optical properties such as optical absorption and PL, and electrical properties have been measured.

26. Amorphous and Microcrystalline Silicon

Processes used to grow hydrogenated amorphous silicon (a-Si:H) and microcrystalline silicon ($\mu\text{c-Si:H}$) from SiH_4 and H_2/SiH_4 glow discharge plasmas are reviewed. Differences and similarities between growth reactions of a-Si:H and $\mu\text{c-Si:H}$ in a plasma and on a film-growing surface are discussed, and the process of nucleus formation followed by epitaxial-like crystal growth is explained as being unique to $\mu\text{c-Si:H}$. The application of a reaction used to determine the dangling-bond defect density in the resulting a-Si:H and $\mu\text{c-Si:H}$ films is emphasized, since it can provide clues about how to improve the optoelectronic properties of those materials for device applications, especially thin-film silicon-based solar cells. Material issues related to the realization of low-cost and high-efficiency solar cells are described, and finally recent progress in this area is reviewed.

Hydrogenated amorphous silicon (a-Si:H) and microcrystalline silicon ($\mu\text{c-Si:H}$) are recognized as being useful materials for constructing devices related to optoelectronics, such as solar cells, thin-film transistors, etc. [26.1, 2]. Several methods have been proposed for the preparation of device-grade a-Si:H and $\mu\text{c-Si:H}$. These include: reactive sputtering of a crystalline silicon target with $\text{Ar}+\text{H}_2$ plasma [26.3]; mercury-sensitized photochemical vapor deposition (CVD) utilizing a decomposition reaction of silane (SiH_4) molecules with photoexcited Hg (Hg^*) [26.4]; a direct photo CVD method where high-energy photons from a Xe-resonance lamp or a low-pressure Hg lamp are used for the direct excitation of SiH_4 molecules to excited electronic states [26.5, 6]; a hot-wire CVD method for

decomposing SiH_4 by means of catalytic reactions on a heated metal surface [26.7]; and a plasma-enhanced CVD method (PECVD). The PECVD method is the most widely used of these due to its ability to consistently prepare uniform, high-quality materials on a large-area substrate.

In this chapter, the PECVD method is highlighted, details regarding the processes used to grow a-Si:H and $\mu\text{c-Si:H}$ from reactive plasmas are explained, and the determination reaction (which is used to obtain the dangling-bond defect density in the films: one of the most important structural properties that influences device performance) is interpreted in order to obtain clues about how to control the optoelectronic properties of those materials for device applications.

26.1 Reactions in SiH_4 and SiH_4/H_2 Plasmas

The initial event required for the growth of a-Si:H and $\mu\text{c-Si:H}$ is the decomposition of the source gas material in SiH_4 or SiH_4/H_2 glow discharge plasma. Figure 26.1 shows a schematic of the dissociation pathway of SiH_4

and H_2 , during which the molecules are excited to higher electronic states due to inelastic collisions with high-energy electrons in the plasma [26.8]. As the electrons in the plasma usually have a wide variety of energies,

Fig. 26.1 Schematic showing the dissociation of SiH_4 and H_2 molecules to a variety of chemical species in the plasma via excited electronic states. The electron energy distribution function in the plasma is also shown

from zero to several tens of electron volts (eV), ground-state electrons of source gas molecules are excited into their electronic excited states almost simultaneously due to inelastic collisions with energetic electrons. Excited electronic states of complicated molecules like SiH_4 are usually dissociating states, from which dissociation occurs spontaneously to SiH_3 , SiH_2 , SiH , Si , H_2 and H , as shown in Fig. 26.1, depending on the stereochemical structure of the excited state. Hydrogen molecules are also decomposed to atomic hydrogen. Excitation of ground-state electron to vacuum-state gives rise to ionization events, generating new electrons and ions, which maintains the plasma.

Reactive species produced in the plasma also experience secondary reactions, mostly with parent SiH_4 and H_2 molecules, as shown in Fig. 26.2, resulting in a steady state. Reaction rate constants for each reaction are summarized in the literature [26.9]. Steady-state densities of reactive species are basically determined by the balance between their rate of generation and their annihilation rate. Therefore, highly reactive species such as SiH_2 , SiH and Si (short-lifetime species) have much smaller densities than SiH_3 in the steady-state plasma, although the generation rates of those species are not very different from that of SiH_3 , which shows low reactivity along with SiH_4 and H_2 (long-lifetime species).

Steady-state densities of reactive species have been measured using various gas-phase diagnostic techniques [26.10–16], such as optical emission

spectroscopy (OES) [26.10], laser-induced fluorescence (LIF) [26.12], infrared laser absorption spectroscopy (IRLAS) [26.13], and ultraviolet light absorption spectroscopy (UVLAS) [26.16]. Figure 26.3 shows the steady state number densities of the chemical species, including both emissive and ionic species, in the SiH_4 and SiH_4H_2 plasmas used to prepare device-grade a-Si:H and $\mu\text{c-Si:H}$. It is clear from Fig. 26.3 that the SiH_3 radical is the dominant chemical species in the growth of both a-Si:H and $\mu\text{c-Si:H}$, although the density ratio of short-lifetime species to SiH_3 changes depending on the conditions used to generate the plasma. For instance, when high electric power is supplied to the plasma (high electron density) under low SiH_4 flow

rate conditions, SiH_4 is rapidly dissociated and then depleted, giving rise to reduced probabilities of gas-phase reactions of short lifetime species with SiH_4 molecules. This leads to an increased contribution from short-lifetime species to the film growth, which causes a deterioration of the structural properties of the resulting films.

The steady-state density of atomic hydrogen (H) varies widely in the plasma, as shown in Fig. 26.3. This is mainly due to the change in the hydrogen dilution ratio R (H_2/SiH_4 in the source gas material, i.e., the density of atomic hydrogen increases with increasing R . Noting the fact that more $\mu\text{c-Si:H}$ is formed with increasing R at constant electron density in the plasma and constant substrate (surface) temperature, it is clear

Fig. 26.3 Number densities of chemical species in realistic steady-state plasmas measured or predicted by various diagnostic techniques

that atomic hydrogen plays an important role in $\mu\text{c-Si:H}$ growth [26.17] although SiH_3 is the dominant film precursor for both a-Si:H and $\mu\text{c-Si:H}$ growth [26.18].

26.2 Film Growth on a Surface

26.2.1 Growth of a-Si:H

Upon reaching a film-growing surface, SiH_3 radicals begin to diffuse across it. During this diffusion, the SiH_3 abstracts bonded hydrogen from the surface, forming SiH_4 and leaving dangling bonds on the surface (this known as growth site formation). Other SiH_3 molecules then diffuse across the surface to find the site containing the dangling bonds, whereupon Si–Si bond formation (film growth) occurs, as shown schematically in Fig. 26.4. This surface reaction scheme for film growth has been proposed on the basis of two experimental results [26.18].

Fig. 26.4 Schematic of the surface growth of a-Si:H

Figure 26.5 shows the general concept of the surface reaction process. Some the flux of SiH_3 is reflected off the surface (the proportion of molecules reflected is given by the reflection probability). The remaining SiH_3 is adsorbed onto the surface and it changes its form as follows:

1. SiH_3 abstracts bonded H from the surface, forming SiH_4 , or two of the SiH_3 radicals interact on the surface, forming Si_2H_6 (with a recombination probability γ);
2. Surface-diffusing SiH_3 sticks to the site containing the dangling bond, forming Si–Si bond (with a sticking probability s).

The total loss probability (β) is given by the sum of recombination probability and the sticking probability ($\gamma + s$), and the reflection probability is therefore $1 - \beta$. Among the reaction probabilities mentioned above, the

Fig. 26.5 General concepts behind the surface reactions of incoming SiH_3 radicals

Fig. 26.6a,b Loss probability β (a) of SiH_3 radicals reaching the film-growing surface, as measured using the grid method and the step-coverage method, and the deposition rate (corresponding to the sticking probability s for SiH_3) (b) as a function of substrate temperature during the formation of a-Si:H

Fig. 26.7 Crystal size (light: δ) and volume % (dark: X_c) of microcrystallites in the resulting films, mapped out on the RF power density/hydrogen dilution ratio plane

loss probability has been measured using a grid method (GM) as well as a step-coverage method (SCM). Figures 26.6a and 26.6b show the loss probabilities obtained by GM and SCM, as well as the sticking probability pre-

dicted from the film deposition rate as a function of the substrate temperature, respectively.

The loss probability β , related to the reflectivity ($1 - \beta$), is simply dependent on the nature of the site where SiH_3 from the plasma lands. Therefore, the temperature-independent $1 - \beta$ seen in Fig. 26.6 suggests that almost all of the surface sites are covered with bonded H over the whole temperature range used in the experiment, although a few dangling bonds are created thermally above 350°C, as shown by in situ infrared reflection absorption spectroscopy (IR-RAS) [26.19]. On the other hand, SiH_3 diffusing across the surface is easily captured by even just a few dangling bonds, because a mobile species on the surface can find a specific site at a distant location from the landing site.

The temperature-independent behavior of $1 - \beta$ and the temperature-dependent behavior of s observed in Figs. 26.6a and 26.6b have been perfectly reproduced by theoretical simulations based on the surface-reaction scheme shown in Fig. 26.4, assuming reasonable activation energies for the surface diffusion of SiH_3 , the abstraction reaction of H with SiH_3 , the saturation of the site containing the dangling bond with SiH_3 , and thermal H-removal processes [26.20].

26.2.2 Growth of $\mu\text{c-Si:H}$

Atomic hydrogen reaching the film-growing surface plays an important role in the growth of $\mu\text{c-Si:H}$. This has been confirmed in the $\mu\text{c-Si:H}$ -formation map draw-

Fig. 26.8 Volume % (X_c) of microcrystallites in the resulting films plotted against the substrate temperature during film growth

ing on the RF power density/hydrogen diffusion ratio plane as shown in Fig. 26.7. As seen in the figure, large-crystallite $\mu\text{c-Si:H}$ is prepared under high hydrogen dilution conditions, indicating the importance of atomic H in the growth of $\mu\text{c-Si:H}$. Figure 26.8 shows the crystalline volume fraction (determined by the X-ray diffraction peak area) in the resulting $\mu\text{c-Si:H}$ as a function of the substrate temperature during film growth for three different hydrogen dilution ratios [26.17]. The crystalline volume fraction increases with increasing substrate temperature, reaching a maximum at around 350 °C, and then suddenly drops to zero above 500 °C. The lack of $\mu\text{c-Si:H}$ formation above 500 °C suggests that surface hydrogen coverage is a requirement for crystallite formation in the resulting film [26.17].

Figure 26.9 shows the negative effect of ionic species impinging on the film-growing surface on the formation of $\mu\text{c-Si:H}$, studied using a triode reactor, as shown in the inset of the figure [26.21]. The Raman crystallinity I_c/I_a , defined as the ratio of the peak intensity from the crystalline phase at around 520 cm^{-1} to that from the amorphous phase at 480 cm^{-1} in the Raman scattering spectrum, deteriorates as the energy of the ionic species impinging on the film-growing surface (controlled by the bias voltage applied to the mesh electrode) is increased.

The surface reaction behavior of SiH_3 reaching the film-growing surface has also been investigated for $\mu\text{c-Si:H}$ growth using GM and SCM, in contrast to a-Si:H growth [26.18]. Figures 26.10a and 26.10b show the loss probability (β) and the deposition rate (corresponding to the sticking probability s) of SiH_3 reaching the

Fig. 26.9 Raman crystallinity in the resulting $\mu\text{c-Si:H}$ as a function of the energy of the ions impinging on the film-growing surface (which is controlled by the application of the bias voltage to the mesh electrode during film growth)

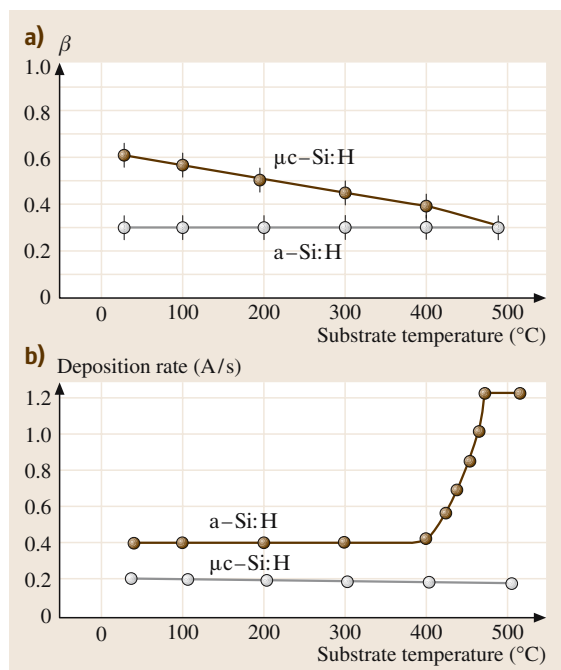

Fig. 26.10 Loss probability β and deposition rate as a function of substrate temperature for $\mu\text{c-Si:H}$ growth in comparison to those for a-Si:H growth

film-growing surface as a function of the substrate temperature for the growth of both $\mu\text{c-Si:H}$ and a-Si:H.

Fig. 26.11 Surface diffusion model for $\mu\text{c-Si:H}$ formation. The large spheres and small spheres represent Si and H, respectively

Fig. 26.12 Etching model for $\mu\text{c-Si:H}$ formation

Fig. 26.13 Chemical annealing model for $\mu\text{c-Si:H}$ formation

Unlike in the case of a-Si:H growth, the loss probability β shows a significant dependence on substrate temperature and the sticking probability s shows no temperature dependence in the case of $\mu\text{c-Si:H}$ growth.

Based on these experimental results, the following properties of the formation process of $\mu\text{c-Si:H}$ can be specified:

1. The film precursor is SiH_3 , the same as in the case of a-Si:H growth;
2. Atomic hydrogen reaching the film-growing surface plays an important role in the formation of $\mu\text{c-Si:H}$;
3. The film becomes amorphous when the substrate temperature is higher than 500°C ;
4. High-energy ions impinging on the surface result in crystallinity deterioration;
5. The surface loss probability shows a temperature dependence whereas the sticking probability does not show a temperature dependence in the case of $\mu\text{c-Si:H}$ growth.

Growth Models for $\mu\text{c-Si:H}$

In an attempt to explain the specific phenomena observed during the formation of $\mu\text{c-Si:H}$, three models have been proposed:

1. The surface diffusion model [26.17];
2. The etching model [26.22];
3. The chemical annealing model [26.23].

The surface diffusion model is depicted schematically in Fig. 26.11. Here, a high atomic H flux from the plasma results in full bonded hydrogen surface coverage and also local heating through hydrogen exchange reactions on the film-growing surface. These two actions enhance the surface diffusion of film precursors (SiH_3). As a consequence, the SiH_3 adsorbed on the surface can find energetically favorable sites, leading to the formation of an atomically ordered structure (nucleus formation). After the formation of the nucleus, epitaxial-like crystal growth takes place with enhanced surface diffusion of SiH_3 [26.17, 24].

The etching model has been proposed due to the observation that the rate of film growth decreases with increasing hydrogen dilution ratio R . The concept behind the etching model is shown schematically in Fig. 26.12. Atomic H reaching the film-growing surface breaks Si–Si bonds, preferentially weak bonds involved in the amorphous network structure, leading to the removal of Si atoms weakly bonded to other Si atoms. This site is replaced with a new film precursor SiH_3 , creating a rigid, strong Si–Si bond, which gives rise to an ordered structure [26.22, 24].

The chemical annealing model has been proposed in order to explain the observation that crystal formation is observed during hydrogen plasma treatment;

growth occurs layer-by-layer via an alternating sequence of thin amorphous film growth and hydrogen plasma treatment. Several monolayers of amorphous silicon are deposited, and these layers are exposed to hydrogen atoms produced in the hydrogen plasma. This procedure is repeated several tens of times in order to fabricate the proper thickness to be able to evaluate the film structure. The absence of any significant reduction in film thickness during the hydrogen plasma treatment is difficult to explain using the etching model, and so the chemical annealing model was proposed, as schematically shown in Fig. 26.13. During the hydrogen plasma treatment, many atomic hydrogens permeate through the subsurface (the growth zone), giving rise to the crystallization of an amorphous network through the formation of a flexible network without any significant removal of Si atoms [26.23, 24].

These three models have been carefully examined, and the merits and drawbacks of each model have been discussed [26.24, 25].

More microscopic observations have recently been reported, based on the use of in situ diagnostic techniques, and a detailed mechanism for the formation process of $\mu\text{c-Si:H}$ has been proposed.

Formation of the Nucleus

Figure 26.14 shows the evolution in surface roughness during film growth, as obtained by spectroscopic ellipsometry (SE), for three hydrogen dilution ratios R of 0, 10 and 20 [26.26]. As is seen in the figure, after the formation of an island, the enforced coalescence of islands takes place, which results in a smooth surface under

Fig. 26.14 Evolution in surface roughness, as measured using spectroscopic ellipsometry, during film growth for three different R_s

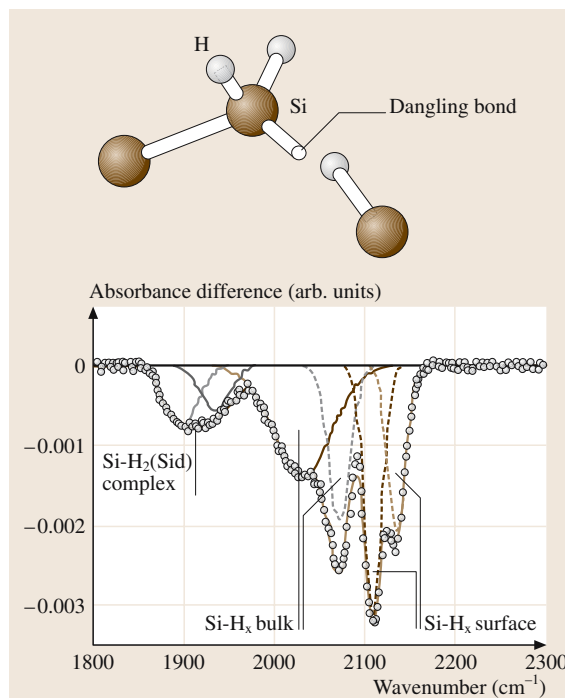

Fig. 26.15 Surface infrared absorption spectrum from the film just before nucleus formation, showing the appearance of the $\text{Si-H}_2\text{-d}$ complex whose structure is also shown

$\mu\text{c-Si:H}$ -growth conditions ($R = 20$). After the smooth surface is obtained (formation of the nucleus is confirmed at this point in time), surface roughness is then enhanced due to an orientation-dependent crystal growth rate [26.27]. As soon as the smooth surface appears, a particular surface absorption band is observed in the infrared absorption spectrum, as measured using the in situ attenuated total reflection technique (ATR) during film growth [26.27, 28]. Figure 26.15 shows the surface infrared absorption spectrum, showing the presence of specific bands at 1897 cm^{-1} and 1937 cm^{-1} together with the usual Si-H_x surface and bulk absorption bands (which occur between 2000 cm^{-1} and 2150 cm^{-1}). This new absorption band is assigned to the $\text{SiH}_2(\text{Sid})$ complex, which is also sketched in Fig. 26.15. Note that the number density (absorption intensity) of the $\text{SiH}_2(\text{Sid})$ complex is found to be proportional to the magnitude of the internal stress in the film just before these complexes appear. A nucleation model has been proposed based on the experimental facts mentioned above. The enforced island coalescence due to the enhanced surface diffusion of SiH_3 gives rise to an internal stress involving many strained Si-Si bonds in the amorphous

incubation layer [26.27]. Atomic hydrogen attacks the strained Si–Si bonds, forming $\text{SiH}_2(\text{Sid})$ complexes on the film-growing surface. These complexes provide structural flexibility, which enables structural order to be obtained via successive Si– SiH_3 bond formation at this site; in other words it acts as a prenucleation site on the film-growing surface.

Epitaxial-Like Crystal Growth

Figure 26.16 shows a cross-sectional transmission electron microscope (TEM) image of typical $\mu\text{c-Si:H}$ films deposited on a glass substrate [26.29]. In the figure, epitaxial-like crystal growth is clearly observed to occur from the nucleus. It is a well-known fact that epitaxial crystal growth occurs only when the surface diffusion length of the film precursor is sufficiently long. In order to investigate the origin of the enhanced surface diffusion of SiH_3 during the formation of $\mu\text{c-Si:H}$, an isotope labeling experiment has been carried out [26.30]. D_2 was used as the source gas material (D_2SiH_4) instead of H_2SiH_4 during film growth under constant substrate temperature conditions, and the number densities of both D and H incorporated into the resulting film are measured by infrared absorption spectroscopy in order to estimate the degree of H-to-D exchange reactions, which mostly occur on the film-growing surface.

Figure 26.17 shows the Raman crystallinity I_c/I_a plotted against the number density ratio of the D/H incorporated in the resulting films. As is clearly from the figure, $\mu\text{c-Si:H}$ is obtained only when D/H exceeds a critical value, indicating that the D/H exchange reaction is required to some extent for the formation of $\mu\text{c-Si:H}$. The D/H exchange reaction involves two steps:

1. Atomic D reaching the film-growing surface abstracts bonded H on the surface (the Eley-Rideal reaction), forming HD and providing a Si dangling bond site;
2. A recombination reaction occurs between the dangling bond and another atomic D adsorbed onto the surface, forming a Si–D bond.

These abstraction and recombination reactions are known to be strong exothermal reactions, with 1.4 eV and 3.1 eV of energy released, respectively. Considering the highly exothermal nature of the D/H exchange reaction, and the existence of a threshold value for the degree of D/H exchange reactions required for the formation

Fig. 26.16 Cross-sectional transmission electron microscope image of typical $\mu\text{c-Si:H}$ deposited on a glass substrate

Fig. 26.17 Raman crystallinity plotted against the number density ratio of D/H incorporated into the resulting films prepared from D_2SiH_4 plasmas

of $\mu\text{c-Si:H}$, as shown in Fig. 26.17, “local heating” on the film-growing surface is believed to play a major role in the enhanced surface diffusion of the film precursor (SiH_3) during both nucleus formation (strained bond formation and $\text{SiH}_2(\text{Sid})$ -complex formation) and the epitaxial-like crystal growth associated with $\mu\text{c-Si:H}$ film growth [26.17, 24, 28, 31].

26.3 Defect Density Determination for a-Si:H and $\mu\text{c-Si:H}$

One of the most important structural properties of a-Si:H and $\mu\text{c-Si:H}$ for device applications is their dangling bond defect densities, because each dangling bond creates a localized deep state in the band gap of the material, which acts as a recombination center for photoexcited electrons and holes, although the free carrier mobility is another important property in semiconductors.

26.3.1 Dangling Bond Defects

Figure 26.18 shows the dangling bond defect density in the resulting a-Si:H as a function of substrate temperature. This dependency of the dangling bond density on the substrate temperature has been explained by taking into account the steady-state dangling-bond density on the film-growing surface. The structural properties of the resulting film are generally largely determined by the steady-state surface properties during the thin film growth process, because the surface formed at any given instant is incorporated into the bulk in the next instant due to the successive layering nature of the film growth [26.32, 33]. The steady state number density of surface dangling bonds is determined by the balance between the rate of generation of dangling bonds and their annihilation rate.

At low substrate temperatures, surface dangling bonds are produced by abstraction reactions of surface H atoms with SiH_3 ; the reaction rate for this is almost independent of substrate temperature, since the reaction rate is affected by both the residence time of

SiH_3 at the H-covered site (longer residence times occur at lower temperatures) and by the abstraction reaction rate (slower rates occur at lower temperatures). The surface dangling bond is saturated by SiH_3 diffusing across the surface (this is dangling bond annihilation), which exhibits a slower rate at low temperatures due to the slower surface diffusion of SiH_3 , which results in high dangling bond density on the steady-state film-growing surface. As a consequence, the dangling-bond density in a-Si:H grown at low substrate temperatures can be as high as 10^{19} cm^{-3} . When the substrate temperature is increased during film growth, the steady state number density of surface dangling bonds is reduced drastically due to the combination of the temperature-independent H-abstraction reaction and the thermally enhanced surface diffusion of SiH_3 , which gives rise to a minimum defect density of 10^{15} cm^{-3} in the resulting a-Si:H at a substrate temperature of $\approx 250^\circ\text{C}$. The increased dangling bond density of the a-Si:H prepared at substrate temperatures higher than 350°C is explained by the increased rate of generation of steady-state dangling bonds due to the addition of a new term in the generation rate of these bonds associated with the thermal removal of surface H, although its annihilation rate strictly increases with increasing substrate temperature [26.33, 34].

We note here that a remarkable increase in the contribution from short-lifetime species such as SiH_2 , SiH and Si , which show high reactivity and no diffusion on the film-growing surface, is observed upon the depletion of SiH_4 -parent molecules, which causes an increase in the

Fig. 26.18 Dangling bond defect density in the resulting a-Si:H films as a function of the substrate temperature during film growth

Fig. 26.19 Dangling bond defect density in a-Si:H films plotted against their deposition rates for three different substrate temperatures

number density of dangling bond defects in the resulting films through an enhancement of the dangling bond generation rate and a reduction of the dangling bond annihilation rate on the film-growing surface [26.20,32].

Based on our understanding of the defect density determination reaction during film growth, several trials have attempted to control the defect density in a-Si:H. The steady state defect density on the film-growing surface could be reduced when the growth rate was much faster than the thermal H removal rate in the substrate temperature range above 350 °C, where the steady state defect density is mainly determined by the thermal H removal process. Figure 26.19 shows the number density of dangling bond defects in a-Si:H films plotted against their growth rate. As expected, the defect density in a-Si:H shows no growth-rate dependence when the film is prepared at substrate temperatures lower than 300 °C, whereas the defect density monotonically decreases with increasing growth rate when the film is deposited at 400 °C and 450 °C, and a defect density of 10^{14} cm^{-3} has been demonstrated [26.35].

26.3.2 Dangling Bond Defect Density in $\mu\text{c-Si:H}$

Figure 26.20 shows typical dangling bond defect densities in $\mu\text{c-Si:H}$ as a function of substrate temperature together with those in its a-Si:H counterpart [26.33,35,36]. As seen from the figure, the substrate temperature-dependent dangling bond defect density in $\mu\text{c-Si:H}$ in the temperature range above 300 °C shows a similar trend to that for a-Si:H, indicating that the defect determination reaction on the film-growing surface is identical for both $\mu\text{c-Si:H}$ and a-Si:H growth in this temperature range; in other words, the increase in defect density with increasing substrate temperature is controlled by the thermal

Fig. 26.20 Dangling bond defect density in $\mu\text{c-Si:H}$ films as a function of substrate temperature during film growth in comparison to that in a-Si:H

H removal process on the film-growing surface. On the other hand, the number density of defects in $\mu\text{c-Si:H}$ prepared at low substrate temperatures shows much lower values than those in a-Si:H. Considering that the defect density in the resulting film is largely determined by the defect density on the steady-state film-growing surface, the much lower defect density in $\mu\text{c-Si:H}$ is caused by an increase in the defect annihilation rate on the film-growing surface due to the local heating from H-exchange reactions that occur during the course of $\mu\text{c-Si:H}$ film growth.

It should be noted here that the dangling bond defect density in the resulting $\mu\text{c-Si:H}$ is strongly influenced by the ion bombardment during film growth and by the collisions of crystals growing from different nuclei, which are different aspects to those that are important during a-Si:H growth.

26.4 Device Applications

a-Si:H and $\mu\text{c-Si:H}$ are highly promising materials applicable to electronic or optoelectronic thin-film devices such as thin-film transistors (TFT), position sensors, color sensors, solar cells, etc. [26.1,2].

A thin-film transistor array with a-Si:H active layer has been developed for switching devices in liquid crystal displays (LCD), and large-area LCDs more than 40 in across have already been made commercially available based on this technology. A laser crystallization technique has been developed in order to increase the carrier mobility of a-Si:H-based TFTs and thus reduce the ac-

tive area of the transistors in the LCD. LCDs with a-Si:H or laser-crystallized thin-film Si-based transistor arrays are widely used as flat panel displays in televisions and monitors, where they are in competition with plasma display panels (PDP) and other flat panel display systems. If the carrier mobility in as-deposited $\mu\text{c-Si:H}$ is drastically improved through the enhanced control of the film growth process, $\mu\text{c-Si:H}$ will be widely used not only for thin-film transistors but also for signal-scanning devices such as charge-coupled devices monolithically arranged in the periphery of the LCD.

Thin-film Si-based solar cells has also been widely expected to provide low-cost photovoltaics. Actually, a-Si:H-based solar cells have already been widely used in pocket calculators, and now large-area solar cells are being developed for electricity generation. One big advantage of using a-Si:H for solar cell applications is its large optical absorption coefficient compared to single-crystalline or polycrystalline silicon counterparts, resulting in indirect optical transition properties, and so a thickness of less than $1\ \mu\text{m}$ is enough to absorb sufficient sunlight for electricity generation when using a-Si:H-based solar cells. Low-temperature processes using PECVD are also advantageous in terms of reducing the cost of producing a-Si:H-based solar cells. However, there is a well-known phenomenon that occurs in a-Si:H called photo-induced degradation [26.37], where the conversion efficiency of a-Si:H-based solar cells, usually $\approx 10\%$, is degraded to less than 8% after prolonged exposure to light. Recombinations photo-generated electrons and holes are believed to trigger this photoinduced degradation in a-Si:H; therefore, increasing the field in the a-Si:H-based solar cell has proved an effective way to reduce the degradation. In fact, $0.1\ \mu\text{m}$ -thick a-Si:H-based solar cells do not show

any photoinduced degradation, although the conversion efficiency naturally deteriorates due to the reduced absorption of sunlight. The fabrication of a tandem-type stacked solar cell structure consisting of a top cell with a thin a-Si:H layer and a bottom cell containing narrow-gap materials such as a-SiGe:H, $\mu\text{c-Si:H}$ and $\mu\text{c-SiGe:H}$ has been proposed as a promising way to overcome photoinduced degradation and so to achieve high conversion efficiency in thin-film silicon-based solar cells. Initially, a-SiGe:H was adopted for the bottom cell material [26.38]; however, this material also shows severe photoinduced degradation. Recently, $\mu\text{c-Si:H}$ or $\mu\text{c-SiGe:H}$ have been proposed as promising candidates for bottom cell materials, because these materials do not exhibit photoinduced degradation [26.39,40]. In this proposal, high rates of growth of those materials are crucial to the low-cost fabrication of tandem-type solar cells, since $\mu\text{c-Si:H}$ and $\mu\text{c-SiGe:H}$ undergo largely indirect optical transitions. Therefore, urgent material issues for the realization of low-cost/high-efficiency thin-film silicon-based solar cells include the need to improve the photoinduced stability of high-quality a-Si:H and the need to achieve a high rate of growth of device-grade $\mu\text{c-Si:H}$ or $\mu\text{c-SiGe:H}$.

26.5 Recent Progress in Material Issues Related to Thin-Film Silicon Solar Cells

26.5.1 Controlling Photoinduced Degradation in a-Si:H

A relationship between the degree of photoinduced degradation and the dihydride bonding (Si-H_2) density has been reported in a-Si:H prepared under a variety of deposition conditions, where the substrate temperature, plasma-excitation frequency, gas-flow rate, hydrogen dilution ratio, working pressure, power density, etc. have all been varied [26.41]. Figure 26.21 shows the degree of photoinduced degradation, defined as the difference in the fill factors of photo-I-V characteristics of Ni-a-Si:H Schottky diode before and after light soaking plotted

against the Si-H_2 density in a-Si:H film, as measured by infrared absorption spectroscopy. Furthermore, it has been suggested from mass spectrometric results that the Si-H_2 density in the resulting a-Si:H is strongly in-

Fig. 26.21 Relationship between the degree of photoinduced degradation and the dihydride (Si-H_2) content in a-Si:H prepared under various deposition conditions. The star symbol represents for a-Si:H prepared under conditions of a reduced ratio of contributions from higher silane-related species versus the SiH_3 contribution at a substrate temperature of 250°C

Fig. 26.22 Surface reaction image of the incorporation of Si–H₂ bonds into the resulting a-Si:H due to the contributions from higher silane-related species such as Si₄H₉

Fig. 26.23 Photo-I–V characteristics of a stable n–i–p a-Si:H-based solar cell fabricated at a high growth rate of 2 nm/s

creased by the contributions from higher silane-related species (HSRS) such as Si₄H₉ when the substrate temperature is kept constant. The contribution of these HSRS to the film precursor (SiH₃) has been theoretically analyzed using a couple of gas-phase reaction-rate equations [26.42]. This analysis predicted that the contribution ratio is a complex function of the electron temperature in the plasma, the electron density in the plasma, the gas temperature, the hydrogen dilution ratio R , and the gas residence time during film growth. Based on our understanding of the network structure (Si–H₂ bonding configuration) responsible for the photoinduced degradation in a-Si:H and the chemical species (HSRS) responsible during film growth (shown schematically in Fig. 26.22), a guiding principle for obtaining highly stabilized a-Si:H has been proposed [26.42, 43].

By following the guiding principle, a-Si:H with minimized Si–H₂ density in the network has been prepared by adjusting the plasma parameters during film growth

under high growth rate conditions, and an a-Si:H-based solar cell showing a stable conversion efficiency of 8.2% (Fig. 26.23) has been fabricated at a high growth rate of 2 nm/s [26.41].

Moreover, a-Si:H containing a Si–H₂ density of 0% has been successfully prepared using a triode reactor at substrate temperatures as low as 250 °C by making use of the difference in the gas phase diffusion coefficients of SiH₃ (light) and HSRS (heavy) during film growth.

26.5.2 High Growth Rates of Device-Grade μ c-Si:H

In the past, conventional high hydrogen dilution methods performed at relatively low working gas pressures (several tens of mTorr) have been used to obtain device-grade μ c-Si:H (with low dangling bond defect densities of $\approx 10^{16}/\text{cm}^3$) [26.17]. Recently, a simple concept for preparing device-grade μ c-Si:H at a high growth rate has been proposed, known as the high-pressure depletion (HPD) method [26.21, 44]. The production rate of the film precursor SiH₃ in the plasma, which is proportional to the growth rate of μ c-Si:H, is determined by the product of the electron density and the number density of SiH₄. To increase the production rate of SiH₃ in the plasma, a high power density (radio frequency, RF, or very high frequency, VHF) and high partial pressures are needed, because the electron density is basically a function of the power density applied

Fig. 26.24 Relationships between the dangling bond defect density in μ c-Si:H films and their deposition rates for (A) μ c-Si:H prepared using the conventional low-pressure regime and for (B) μ c-Si:H prepared using the high-pressure depletion (HPD) method. The star symbol represents μ c-Si:H prepared under HPD conditions with the novel cathode design

to the plasma and the number density of SiH_4 is proportional to the partial pressure. However, hydrogen atoms (the chemical species responsible during the formation of $\mu\text{-Si:H}$) are strongly scavenged by SiH_4 molecules during their transportation from their production site to the film-growing surface. In order to enhance the survival of the hydrogen atoms, it has been suggested that the SiH_4 molecules should be depleted by applying high power density to the plasma. As conditions of high total pressure are also useful for decreasing the effects of ion bombardment during film growth through the reduction of the electron temperature in the plasma, high working pressures along with SiH_4 depletion conditions (HPD) have recently been popularly adopted for the high-rate growth of device-grade $\mu\text{-Si:H}$.

Figure 26.24 shows the number density of dangling bond defects, as measured by electron spin resonance (ESR), in the resulting $\mu\text{-Si:H}$ as a function of growth rate [26.45]. When the conventional low pressure regime is used for the growth of $\mu\text{-Si:H}$, the defect density increases exponentially with increasing growth rate, as seen in the figure (see A). This is caused by both an increase in the ion bombardment (due to the high power density) and an increase in the contributions from short-lifetime chemical species such as SiH_2 , SiH and Si due to the reduced ability of those species to react with SiH_4 and H_2 (due to the low pressure and SiH_4 depletion) during film growth. On the other hand, the slope in Fig. 26.24 becomes shallower when HPD conditions are used during the growth of $\mu\text{-Si:H}$, as shown in the figure (see B), which illustrates the usefulness of the HPD method for obtaining high-quality $\mu\text{-Si:H}$ at high growth rates.

The validity of the HPD method has also been demonstrated during the fabrication of $\mu\text{-Si:H}$ -based solar cells. Figure 26.25 shows the photo-I-V characteristics of a $\mu\text{-Si:H}$ -based p-i-n single-junction solar cell prepared at a high growth rate of 2 nm/s using the HPD method, which exhibits a reasonably high conversion efficiency of 8.1% [26.46].

However, HPD conditions require that the spacing between the cathode and anode is reduced in the conventional capacitively coupled plasma reactor, giving rise to nonuniform plasma production and nonuniform film growth. To overcome this problem encountered when using HPD conditions, the structure of the cathode surface has been designed to produce uniform plasma

Fig. 26.25 Photo-I-V characteristics of a p-i-n $\mu\text{-Si:H}$ -based solar cell fabricated at reasonably high growth rate of 2 nm/s under HPD conditions

Fig. 26.26 Photograph of the surface structure on the cathode designed for the production of high-density/uniform plasmas

production even in a large-area parallel plate electrode configuration. Figure 26.26 shows the structure of this novel design of cathode. A multitude of holes (hollows) with interconnecting slots are arranged on the cathode surface, which cause strong coupling between the high-density plasmas produced in each hole where source gas injection is performed. Using this new type of cathode, quite high growth rates (more than 8 nm/s) have been obtained along with reasonably low defect densities in the resulting $\mu\text{-Si:H}$, as shown by star symbol in Fig. 26.24 [26.47].

26.6 Summary

In this chapter, the processes involved in the growth of a-Si:H and μ c-Si:H from SiH₄ and SiH₄H₂ plasma have been interpreted in detail. The defect density determination reaction that takes place on the film-growing surface was discussed in order to obtain clues that may lead to enhanced optoelectronic properties in those materials. The recent status of work done in the fields of thin-film transistors and solar cells was reviewed, as these are

the main device applications of those materials. Recent progress in resolving material issues related to solar cell applications were also described.

Finally, we note here that the concepts used in and our understanding of the film growth process mentioned here are widely applicable to other processes, especially processes where thin films are grown from reactive plasmas.

Ferroelectric

27. Ferroelectric Materials

Ferroelectric materials offer a wide range of useful properties. These include ferroelectric hysteresis (used in nonvolatile memories), high permittivities (used in capacitors), high piezoelectric effects (used in sensors, actuators and resonant wave devices such as radio-frequency filters), high pyroelectric coefficients (used in infra-red detectors), strong electro-optic effects (used in optical switches) and anomalous temperature coefficients of resistivity (used in electric-motor overload-protection circuits). In addition, ferroelectrics can be made in a wide variety of forms, including ceramics, single crystals, polymers and thin films – increasing their exploitability. This chapter gives an account of the basic theories behind the ferroelectric effect and the main ferroelectric material classes, discussing how their properties are related to their composition and the different ways they are made. Finally, it reviews the major applications for this class of materials, relating the ways in which their key functional properties

affect those of the devices in which they are exploited.

27.0.1 Definitions and Background

Ferroelectric materials offer a very wide range of useful properties for the electronic engineer to exploit. As we will see, they are also a class of materials that is hard to define accurately in a single sentence. It is useful to start from the class of insulating materials that form dielectrics; in other words materials that will sustain a dielectric polarisation under the application of an electric field. There exists a set of these materials for which the crystal structure lacks a centre of symmetry. (If a crystal structure has a centre of symmetry, it means that for every atom in the structure there is a point in the unit cell through which inversion will bring one to the same type of atom.) A list of the non-centrosymmetric, or *acentric*, point groups is given in Table 27.1. All of the crystalline materials whose structures possess these point groups (with the exception of group 432) exhibit the phenomenon of piezoelectricity, which means that stress will generate a charge separation on the faces of

the crystal (the direct piezoelectric effect) and will undergo mechanical strain when subjected to an electric field (the converse piezoelectric effect). Both effects are widely exploited in electronic devices. A well-known example of a non-centrosymmetric material is the mineral α -quartz, which is used for the piezoelectric resonators employed for frequency filtering and electronic clocks.

Table 27.1 Polar and acentric (non-centrosymmetric) point groups

Crystal system	Polar (acentric)	Nonpolar (acentric)
Triclinic	1	
Monoclinic	2, m	
Orthorhombic	$mm2$	222
Trigonal	3, $3m$	32
Hexagonal	6, $6mm$	$\bar{6}$, $\bar{6}m2$
Tetragonal	4, $4mm$	$\bar{4}$, 422, $\bar{4}2m$
Cubic	None	23, $\bar{4}3m$, 432

A sub-set of the non-centrosymmetric crystals also possess a unique axis of symmetry. These crystals are said to be *polar*. The polar point groups are also listed in Table 27.1. Polar crystals are piezoelectric (as they are acentric) and also exhibit pyroelectricity, which means that a charge separation will appear on their surfaces when their temperature is changed. Polar structures effectively have a dielectric polarisation *built in* to the unit cell of the crystal structure. This is sometimes called a *spontaneous polarisation*. The application of stress or a change in temperature causes a change in this dipole moment and it is this change that causes the separation of charge on the surfaces of the crystal. The direction and magnitude of the spontaneous polarisation in a polar dielectric can be changed by the application of an electric field, but on removal of the field it will return to its zero-field value. A well-known example of a polar dielectric is ZnO, which possesses the wurtzite crystal structure in which Zn^{2+} ions sit in the tetrahedrally coordinated sites between hexagonal close-packed layers of oxygen ions. Thin films of ZnO are widely used for piezoelectric applications.

A sub-set of the set of polar dielectrics exists for which the application of a field of sufficient magnitude will cause the spontaneous polarisation to switch to a different, stable direction. Upon removal of the field the polarisation will not spontaneously return to its original direction and magnitude. These crystals are called *ferroelectric*. We can view the relationships between the sets of ferroelectric, polar, acentric and centrosymmetric dielectrics as shown in the Venn diagram in Fig. 27.1.

The history of ferroelectrics is long, as has been described in the excellent review by Busch [27.1]. Many very distinguished scientists were involved in its early development, including Brewster (who was one of those who studied pyroelectricity), J. & P. Curie (who discovered piezoelectricity), Boltzmann, Pockels and Debye,

to name but a few. Indeed, the term ferroelectricity was first coined by E. Schrodinger. However, credit for the discovery of the effect goes to Joesph Valasek, who found in 1920 that the polarisation of sodium potassium tartrate (Rochelle salt) could be switched by the application of an electric field, thus providing the first demonstration of the process that is the hallmark of ferroelectricity.

A reasonable working definition of ferroelectricity is “a polar dielectric in which the polarisation can be switched between two or more stable states by the application of an electric field”. However, as we will see in the discussion which follows, there are exceptions to this definition: some ferroelectrics are semiconducting (and thus are not dielectrics because they cannot sustain an electrical polarisation); the spontaneous polarisation in some ferroelectrics cannot be switched because they cannot sustain an electric field of sufficient magnitude to effect the switching, either because they reach electrical breakdown first, or because they are too conducting.

Since the initial discovery of ferroelectricity in Rochelle salt, the effect has been demonstrated in a wide range of materials, from water-soluble crystals through oxides to polymers, ceramics and even liquid crystals. Many of these will be discussed in this chapter. The range of useful properties exhibited by ferroelectrics covers:

- Ferroelectric hysteresis is used in nonvolatile computer information storage.
- Ferroelectrics can exhibit very high relative permittivities (several thousand) which means that they are widely used in capacitors.
- The direct piezoelectric effect (the generation of charge in response to an applied stress) is widely used in sensors such as accelerometers, microphones, hydrophones etc.
- The converse piezoelectric effect (the generation of strain in response to an applied electric field) is widely used in actuators, ultrasonic generators, resonators, filters etc.
- The pyroelectric effect (the generation of charge in response to a change in material temperature) is widely used in uncooled infra-red detectors.
- The electro-optic effect (a change in birefringence in response to an applied electric field) is used in laser Q-switches, optical shutters and integrated optical (photonic) devices.
- Ferroelectrics exhibit strong nonlinear optical effects that can be used for laser frequency doubling and optical mixing.

Fig. 27.1 Venn diagram showing how ferroelectrics fit into the different classes of dielectric materials

- Illumination of transparent ferroelectrics with light of sufficient energy causes excitation of carriers into the conduction band. Their movement under the internal bias field caused by the spontaneous polarisation causes a refractive-index modulation that can be used for a variety of optical applications, including four-wave mixing and holographic information storage.
- Ferroelectrics exhibit strong coupling between stress and birefringence, which can be used to couple acoustic waves to optical signals with applications in, for example, radar signal processing.
- Doping certain ferroelectric ceramics with electron donors (e.g. BaTiO₃ with La³⁺) can render them semiconducting. Heating these ceramics through their Curie temperature causes a very large, reversible increase in resistivity (by several orders of magnitude in some cases) over a narrow range of temperature (ca. 10 °C). This large positive temperature coefficient of resistance (PTCR) is widely exploited in electric-motor overload-protection devices and self-stabilising ceramic heating elements.

27.0.2 Basic Ferroelectric Characteristics and Models

The switchable spontaneous polarisation in ferroelectrics gives rise to the first characteristic property of the materials: ferroelectric hysteresis. Figure 27.2 shows a schematic plot of polarisation versus electric field as would be observed on a typical ferroelectric. As the field is increased from zero, the overall polarisation in the crystal increases as the polarisations in different dipolar regions are aligned. Eventually, it reaches a saturation

point where the only further increase in P is that due to the relative permittivity of the material. (The gradient of the P/E curve for a linear dielectric is equal to its permittivity). Extrapolation of this line back to the abscissa gives the saturation value of the spontaneous polarisation (P_s). Reduction of the field to zero leaves a *remanent polarisation* (P_r), which is usually slightly less than P_s . A negative field will cause the polarisation to reduce, until it reaches zero at the *coercive field* ($-E_c$). A further negative increase in the field will eventually cause a reverse saturation polarisation ($-P_s$) to develop. When the field returns to zero the crystal is left with a negative remanent polarisation ($-P_r$). Increasing the field once more, increases the polarisation from $-P_r$ to zero at E_c , and then to $+P_s$, completing the ferroelectric hysteresis loop. The ability to switch the polarisation between two states gives rise to the first application of ferroelectrics – as a nonvolatile memory storage medium. It also permits polycrystalline ferroelectrics (especially ceramics) to be polarised. The fact that the polarisation can possess different directions within different regions of the same crystal gives rise to the existence of *ferroelectric domains*. These are given names according to the angle between the polarisation between adjacent regions. Hence, two adjacent regions in which the polarisations are orientated at 180° to each other are, naturally, called 180° domains. In many ferroelectrics, the polarisation can choose between many different possible directions so that adjacent regions can have polarisations at, for example, 90° to one another.

For most ferroelectrics, the polar state only exists over a limited range of temperatures. As the temperature is raised, a point is reached at which there is a transition from the polar, ferroelectric phase to a non-polar, non-ferroelectric phase (called the *paraelectric* phase). In all cases, the paraelectric phase possesses a higher crystal symmetry than the ferroelectric phase into which it transforms. The temperature at which this occurs is called the *Curie temperature* (T_C). This ferroelectric-to-paraelectric phase transition is a characteristic of most ferroelectrics, but again there are exceptions. Some ferroelectric materials melt or decompose before T_C is reached; the polymeric ferroelectric polyvinylidene fluoride (PVDF) is one such example. For most ferroelectrics (called *proper ferroelectrics*), as the Curie temperature is approached from above, the relative permittivity is observed to increase, reaching a peak at T_C and decreasing below T_C . (There is a class of ferroelectrics, known as *improper* or *extrinsic ferroelectrics*, for which there is no peak in permittivity, just an anomaly. These are described further below.) Very

Fig. 27.2 Ferroelectric hysteresis loop

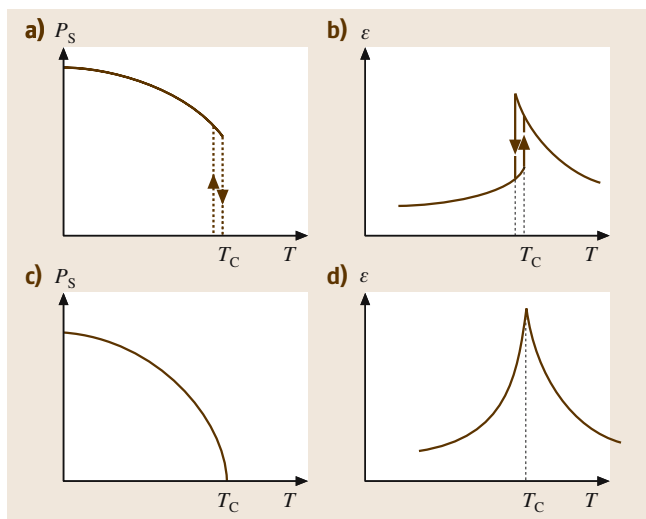

Fig. 27.3a–d The variations of spontaneous polarisation (a and c) and permittivity (b and d) with temperature for typical ferroelectric materials. (a) and (b) are for a first-order (discontinuous) phase transition while (c) and (d) are for a second-order (continuous) phase transition

high values of relative permittivity (many thousands) can be reached at T_C , leading to another use of ferroelectric materials – as dielectrics in high-value capacitors. The phase transition at T_C can either be continuous (known as second-order) or discontinuous (known as first-order). In either case, the dependence of permittivity (ϵ) on temperature above T_C can be described by $\epsilon = C/(T - T_0)$. T_0 is called the *Curie Weiss temperature*, and is only equal to T_C for a second-order phase transition. C is called the *Curie Weiss constant*. Figure 27.3 shows typical plots of P_s and ϵ as functions of temperature for ferroelectrics around T_C . Figs. 27.3a and 27.3b show the behaviour for a first-order phase transition. As can be seen, P_s drops discontinuously to zero at the phase-transition temperature. The permittivity rises as the temperature decreases, peaking at the transition, where there is a discontinuous step down. First-order phase transitions tend to show thermal hysteresis in the transitions, so that the transition occurs at a higher temperature when approached from the low-temperature side than from the high-temperature side. Frequently in practical observations there is actually a region of coexistence where both phases exist together in the same sample at the same temperature. In this case, the Curie temperature is defined as the temperature at which the ferroelectric and paraelectric phases have the same Gibbs free energies. In the case of a second-order phase transition (Figs. 27.3c

and 27.3d), P_s drops continuously to zero at T_C and the permittivity rises to a sharp peak. There is no hysteresis in the transition.

There are two types of theoretical model that describe the ferroelectric phenomenon. The first is the phenomenological or thermodynamic theory first proposed by *Devonshire* [27.2]. Here, the Gibbs free energy of the ferroelectric system is described in terms of a power series in the spontaneous polarisation. In this case, P_s is termed the order parameter for the phase transition and the theory is similar in form to the generalised phenomenological theory of phase transitions known as Landau theory. It is not appropriate to go into the details of the theory here, which has been described very well by *Lines and Glass* [27.3]. The theory successfully predicts many of the behavioural characteristics of ferroelectric materials in terms of the measurable macroscopic properties, including the ferroelectric hysteresis and the behaviour of the permittivity near T_C . However, it tells us nothing about the microscopic origins of ferroelectricity. This is the province of the two types of microscopic models of ferroelectric behaviour. The first of these is the order–disorder model of ferroelectric behaviour. The second is the displacive model.

According to the order–disorder model, the electric dipoles exist within the structure in the paraelectric phase above T_C , but are thermally disordered between two or more states so that the average polarisation is zero. There are several materials for which that is the case, an example being potassium dihydrogen phosphate (KDP), which is paraelectric, tetragonal ($\bar{4}2m$) above 123 K and ferroelectric, orthorhombic ($mm2$) below. The polarisation appears along the tetragonal c -axis. In this crystal structure, the PO_4 groups form tetrahedra that are linked by hydrogen bonds at their corners. The protons in these sit in double potential wells. Above T_C they are delocalised between the two minima in the wells. Below T_C , they are localised and the PO_4 tetrahedra become distorted. The phosphorous and potassium ions become displaced relative to the oxygen framework, forming the polarisation in the lattice. Replacement of the hydrogen in the structure by deuterium raises T_C to about 220 K because the heavier deuteron delocalises between the two potential minima at a much higher temperature. Another example of an order–disorder ferroelectric is sodium nitrite ($NaNO_2$) in which the polar groups are NO_2^- ions, which become ordered below T_C (163 °C) with their dipoles all pointing along the b -axis of the crystal structure.

In displacive ferroelectrics, there are considered to be no dipoles in the structure above T_C , but the dipoles

appear in the structure due to the cooperative motion of ions. Typically this is seen as the *softening* of a zone-centre optical phonon. What this means is that the frequency of an optical phonon mode with zero wavevector goes to zero at T_C . Such a phonon mode involves the displacement in opposite directions of cations and anions in the structure. When the frequency of this mode goes to zero, a dipolar displacement results. Examples of such ferroelectrics include the perovskite-structured oxides such as BaTiO_3 , which will be discussed further below. One of the successes of soft-mode theory is that it provides a convincing mechanism for the peak

in the dielectric permittivity at T_C . According to the Lyddane–Sachs–Teller relationship (see, for example, [27.3] p. 216), the softening of a zone-centre phonon will make the permittivity diverge at T_C .

In practice, the distinction between order–disorder and displacive ferroelectrics becomes rather blurred, as some ferroelectrics which may be considered to be purely displacive may exhibit significant disordered cation displacement well above T_C , while some order–disorder ferroelectrics show soft-mode behaviour. For a more detailed discussion of these theories, the reader is referred to *Lines and Glass* [27.3].

27.1 Ferroelectric Materials

27.1.1 Ferroelectric Oxides

This is by far the most technologically important class of ferroelectric materials. They will be discussed according to the most important crystal classes.

Perovskite Ferroelectrics

These materials possess crystal structures isomorphous with the mineral perovskite (CaTiO_3). They all have the general chemical formula ABO_3 , where A and B are cations. Typically the A cation will be around 1.2–1.6 Å in radius (similar to the oxygen ions) while the B cations

will be around 0.6–0.7 Å in radius. The crystal structure is illustrated in Fig. 27.4. It consists of a network of corner-linked BO_6 octahedra, within which is enclosed the large A cation. Another way to look at the structure is as cubic-close-packed AO_3 layers, with the small B cations sitting in the octahedral sites between these close-packed layers. A pair of layers are shown in Fig. 27.5. The structure is a very tolerant one and will accommodate many different ions. Because of this, it is exhibited by a large number of oxides. The basic criteria for the structure to be stable is that the valencies of the ions should balance and that the ionic radii meet the *Goldschmidt criteria* [27.4]. A tolerance factor t is

Fig. 27.4 The perovskite crystal structure

Fig. 27.5 Showing two AO_3 close-packed layers of the perovskite structure, with the B cations sitting in the sixfold coordinated sites between the layers. The second layer has been made semitransparent for clarity

Table 27.2 List of cations frequently found to form perovskite-structured oxides and their ionic radii. Ionic radii taken from [27.5]

A-site cation	Ionic radius when [12] ^a by O ²⁻ (Å)	B-site cation	Ionic radius when [6] ^b by O ²⁻ (Å)
Na ⁺	1.32	Nb ⁵⁺	0.64
K ⁺	1.6	Ta ⁵⁺	0.68
Ba ²⁺	1.6	Zr ⁴⁺	0.72
Sr ²⁺	1.44	Ti ⁴⁺	0.605
Pb ²⁺	1.49	Pb ⁴⁺	0.775
Bi ³⁺	1.11	Sc ³⁺	0.73
Ca ²⁺	1.35	Fe ³⁺	0.645

^a “12-fold coordinated”; ^b “6-fold coordinated”

defined:

$$t = \frac{r_A + r_O}{\sqrt{2}(r_B + r_O)},$$

where r_X is the ionic radius of the X cation. The ideal cubic perovskite structure, where the ions are just touching each other, will possess $t = 1$. However, the structure will be stable with $0.85 < t < 1.05$. A list of ions that commonly form perovskites, together with their ionic radii, is given in Table 27.2. The closer t is to unity, the more likely the structure will be to be cubic. Conversely, perovskites which have values of $t < 1$ show distorted structures that are frequently ferroelectric. Examples of some perovskites and their tolerance factors are listed in Table 27.3. This table also lists the structures formed by the compounds at room temperature, and whether or not they are ferroelectric. Some of the most interesting perovskites from the point of view of applications are BaTiO₃, PbTiO₃ and KNbO₃. BaTiO₃ is cubic above 135 °C, but transforms to a tetragonal fer-

roelectric structure below this temperature. In this case, the Ba and Ti ions are displaced relative to the anion framework along one of the cubic <001> directions. This means that the polar axis has six choices for direction in the tetragonal phase. At 5 °C there is a second-phase transition from the tetragonal to an orthorhombic phase, where the polarisation now appears due to cation displacements along one of the cubic <110> directions, for which there are 12 choices. Finally, at –90 °C there is a transition to a rhombohedral phase with the cations being displaced along one of the cubic <111> directions, for which there are eight choices. In the case of PbTiO₃ there is a single transition to a tetragonal phase at 490 °C, again by cationic displacements along <100>. Some perovskites show phase transitions that are not ferroelectric. For example, SrTiO₃ shows a transition to a tetragonal phase at 110 K which involves linked rotations, or tilts, of the TiO₆ octahedra about the cubic [100] direction. Tilting of the octahedra is a common feature of the phase transitions that occur in perovskites and can lead to very complex series of phase transitions, as has been observed for NaNbO₃. This type of structural modification and a commonly-used notation for it has been described in detail by Glazer [1972].

It is very easy to make solid solutions of the end-member perovskites, such as those listed in Table 27.3, and this has been used to great effect to provide materials with a wide range of properties. For example, Fig. 27.6 shows the temperature dependence of the relative permittivity of a BaTiO₃ single crystal [27.6]. There is a peak at each transition where the value perpendicular to the polar axis reaches several thousand, making the material interesting for use in capacitor dielectrics. However, the temperature variation in such a material would make it useless. The formation of ceramic solid solutions of BaTiO₃ with SrTiO₃, CaTiO₃ or PbTiO₃ allows the temperature dependence of permittivity to be controlled

Table 27.3 Some end-member perovskites and their properties

Perovskite oxide	Tolerance factor	Structure at 20 °C	Type	T _C (°C)
BaTiO ₃	1.06	Tetragonal	Ferroelectric	135
SrTiO ₃	1.00	Cubic	Paraelectric	
CaTiO ₃	0.97	Tetragonal	Paraelectric	
PbTiO ₃	1.02	Tetragonal	Ferroelectric	490
PbZrO ₃	0.96	Orthorhombic	Antiferroelectric	235
NaNbO ₃	0.94	Monoclinic	Ferroelectric	–200
KNbO ₃	1.04	Tetragonal	Ferroelectric	412
KTaO ₃	1.02	Cubic	Ferroelectric	–260
BiScO ₃	0.83	Rhombohedral	Ferroelectric	370
BiFeO ₃	0.87	Tetragonal	Ferroelectric	850

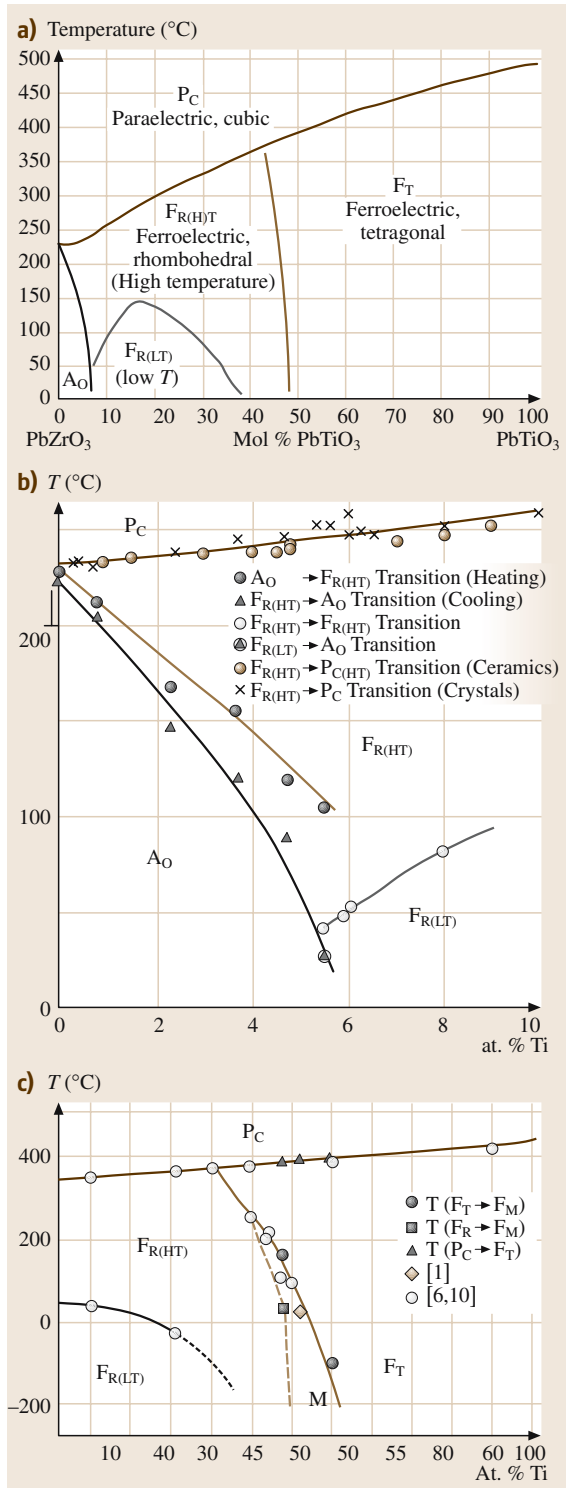

Fig. 27.6 Temperature dependence of the relative permittivity of BaTiO₃ measured along [001] and [100] (After [27.6])

so that useful specifications can be met with average permittivities of 2000 or more over a wide range of temperatures. *Herbert* [27.7] has discussed the details of these modifications and their effects on the BaTiO₃ transition temperatures. BaTiO₃-based ceramics are widely used in ceramic capacitors and form the basis of an industry worth billions of dollars annually. They have also been used for piezoelectric ceramics, but are no longer so important in that field, as they have largely been displaced by ceramics in the PbZrO₃–PbTiO₃ system. Nevertheless, there is a renewed interest in BaTiO₃-based ceramics for lead-free piezoelectrics in response to the legislative drive to reduce lead in the environment.

The perovskite solid solution system between PbZrO₃ and PbTiO₃ is of great technological importance and is thus worth discussing in some detail. The phase diagram given in Fig. 27.7 shows several phases. Starting at PbTiO₃, the ferroelectric tetragonal (F_T) phase persists well across the diagram, until the composition Pb(Zr_{0.53}Ti_{0.47})O₃ is reached, where there is a transition to a ferroelectric, rhombohedral phase. The composition where this occurs is called the morphotropic phase boundary (MPB). The rhombohedral phase region splits into two. There is a high-temperature phase (F_{R(HT)}) in which the cations are displaced along the cubic [111] direction. There is also a low-temperature ferroelectric rhombohedral (F_{R(LT)}) phase in which the (Zr, Ti)O₆

Fig. 27.7 (a) PbZrO₃–PbTiO₃ phase diagram (after [27.8]) (b) Region close to PbZrO₃ (after [27.9, 10]) (c) Region close to the MPB (after [27.11])

octahedra are rotated about the [111] axis. This doubles the unit cell. Close to PbZrO_3 (Fig. 27.7b) the room-temperature structure transforms to the antiferroelectric, orthorhombic (A_0) structure. This is a complex structure in which the cations are displaced in double antiparallel rows along the cubic (110) directions, coupled with octahedral tilts. A higher-temperature A_T phase, which is frequently shown when this phase diagram is cited in the literature, has been shown not to exist in pure solid solutions [27.10]. There is another, more modern, modification to this phase diagram. It has been shown by *Noheda et al.* [27.11] that a monoclinic phase exists at the MPB (Fig. 27.7c). The enormous technological and commercial importance of this system derives from the very high piezoelectric, pyroelectric and electro-optic coefficients that can be obtained from ceramic compositions in different parts of the phase diagram, particularly when the base composition is doped with selected ions. These are discussed in more detail below. This solid solution system is frequently referred to generically as *PZT* although, strictly, *PZT* was the brand name for a set of piezoelectric ceramic compositions manufactured by the Clevite Corporation.

There is another very important class of oxides, termed complex perovskites, where the A or, more commonly B, sites in the structure are occupied by ions of different valency in a fixed molar ratio. These are not solid solutions as they possess a fixed composition. Examples are $\text{PbMg}_{1/3}\text{Nb}_{2/3}\text{O}_3$ (PMN), $\text{PbSc}_{1/2}\text{Ta}_{1/2}\text{O}_3$ (PST) and $\text{Bi}_{1/2}\text{Na}_{1/2}\text{TiO}_3$. These are also technologically important and can form end members to solid solutions in their own right, $\text{PbMg}_{1/3}\text{Nb}_{2/3}\text{O}_3$ – PbTiO_3 (PMN-PT), for example. Many of the complex ferroelectrics (PMN-PT is a classic example) exhibit *ferroelectric relaxor* behaviour. In these materials, the Curie point is no longer a sharp transition but is actually observed over a very wide range of temperatures. A broad permittivity peak is observed and the temperature and height of the peak are strongly dependent on the frequency of measurement. Figure 27.8 shows a typical variation of permittivity with temperature and frequency in PMN [27.12].

The broad tolerance of the perovskite structure to different cations has led to a wide exploration of the inclusion of different iso-valent dopants to obtain different electronic properties. It is also possible to include alio-valent dopants over a wide range, which the structure tolerates through the introduction of cation or anion vacancies, or free charge carriers. For example, it is possible to incorporate Nb^{5+} into the B site of the BaTiO_3 system [27.13], and charge balance is main-

Fig. 27.8 Permittivity (solid lines) and dielectric loss (dashed lines) vs. temperature in PMN. The measurements were made at: (1) 0.4, (2) 45 and (3) 4500 kHz. (Adapted from [27.12])

tained through the presence of free electrons. Similarly, Fe^{3+} can be introduced into the B site of the system and this substitution creates O vacancies [27.14].

The vast majority of perovskites are employed in ceramic form, but thin- and thick-film materials are becoming of increasing importance and single-crystal materials are starting to emerge which have exceptionally high piezoelectric coefficients.

Illmenite Ferroelectrics

The illmenite structure is related to the perovskite structure in that it is exhibited by materials with the general formula ABO_3 , where the A cation is too small to fill the [12] coordinated site of the perovskite structure. The structure is made up of hexagonal close-packed layers of oxygen ions, with the A and B ions occupying the octahedrally coordinated sites between the layers. Hence, this structure can also be considered to be related to the perovskite structure in that both are based on oxygen octahedra. The two best known illmenite ferroelectrics are LiNbO_3 and LiTaO_3 , whose structure is shown in Fig. 27.9. The materials have high T_C values (ca. 1200 °C and 620 °C, respectively). In the case of LiNbO_3 , the T_C is only 50 °C below the melting point.

Fig. 27.9 Crystal structure of LiNbO_3 (after [27.15])

Referring to Fig. 27.9, it can be seen that the cations occupy octahedral sites progressing along the c -axis in the order Nb, vacancy, Li, Nb, vacancy, Li etc. The polarisation occurs through displacement of the cations along the three-fold axis, so the structure transforms from $\bar{3}m$ to $3m$ symmetry at T_C . These are *uniaxial* ferroelectrics, in that the polarisation can only be up or down, and only 180° domains exist. The materials are mainly used in single-crystal form for piezoelectric and electro-optic devices.

Tungsten Bronze Ferroelectrics

This is another very large family of oxygen octahedral ferroelectrics possessing the general formula $[\text{A}_1\text{A}_2\text{A}_4\text{C}_4][\text{B}_1\text{B}_2\text{B}_8]\text{O}_{30}$. The crystal structure is complex, shown schematically in Fig. 27.10. The B1 and B2 sites are octahedrally coordinated by oxygens and have similar sizes and valencies to the B sites in the perovskites. The A1 and A2 sites are surrounded by four and five columns of BO_6 octahedra respectively. The three-fold coordinated C sites in the structure are

Fig. 27.10 Tungsten bronze crystal structure (after [27.16])

frequently empty, but can be occupied by small uni- or divalent cations (e.g. Li^+ or Mg^{2+}). There are a wide range of ferroelectric tungsten bronzes, which frequently show nonstoichiometry. All are tetragonal in their paraelectric phase, and can transform to either a tetragonal ferroelectric phase, in which the polar axis appears along the tetrad axis of the paraelectric phase, or (more commonly) into an orthorhombic phase in which the polar axis appears perpendicular to the original tetrad axis. Examples of tungsten bronzes are PbNb_2O_6 (lead metaniobate) in which five out of the available six A sites are occupied by Pb^{2+} and the B sites by Nb^{5+} . This crystal and its Ta analogue are metastable below about 1200°C . They can be stabilised by rapid cooling, or more commonly by doping. Lead metaniobate ceramics are difficult to make, but are commercially available and are occasionally used for piezoelectric devices by virtue of their higher Curie temperatures than members of the PZT system, combined with reduced lateral piezoelectric coupling factors. Substitution of Pb^{2+} by Ba^{2+} can also be used to produce a useful piezoelectric ceramic material $\text{Pb}_{1/2}\text{Ba}_{1/2}\text{Nb}_2\text{O}_6$. Other tungsten bronze ferroelectrics such as $\text{Sr}_x\text{Ba}_{1-x}\text{Nb}_2\text{O}_6$, $\text{Ba}_2\text{NaNb}_5\text{O}_{15}$ and $\text{K}_3\text{LiNb}_5\text{O}_{15}$ have been investigated as single crystals for use in electro-optic devices. However, the growth of highly homogeneous single crystals is difficult because of the formation of optical striations caused by compositional fluctuations.

Aurivillius Compounds

The aurivillius compounds form another important class of ferroelectrics based on oxygen octahedra. They have a good deal in common with the perovskites in that they consist of layers or slabs of perovskite blocks with the general formula $(A_{m-1}B_mO_{3m+1})^{2-}$ separated by $(M_2O_2)^{2+}$ layers in which the M cation is in pyramidal coordination with four oxygens, the M being at the apex of the pyramid. The structure possesses the general formula $M_2(A_{m-1}B_mO_{3m+3})$. In the ferroelectric phases, M is usually Bi and m is usually between one and five. The A and B cations follow the usual ionic radius and valency criteria of the perovskites, and we see ferroelectric compounds in which A = Bi, La, Sr, Ba, Na, K etc. and B = Fe, Ti, Nb, Ta, etc. Part of the crystal structure is shown schematically in Fig. 27.11, illustrating in this case a structure with $m = 3$. This is just over half of the unit cell, showing one slab of perovskite units and two of the $(Bi_2O_2)^{2-}$ layers. The structures are tetragonal in their paraelectric phases, with the tetrad c -

axis being perpendicular to the $(Bi_2O_2)^{2+}$ plane. In the majority of cases they become orthorhombic in their ferroelectric phase, with the spontaneous polarisation appearing in the $a-b$ plane, at 45° to the tetragonal a -axis. Bismuth titanate ($Bi_4Ti_3O_{12}$) is an example of an aurivillius ferroelectric in which $M = A = Bi$, $B = Ti$ and $m = 3$, so that there are three blocks in the perovskite slab. In this case, there is a small component of the spontaneous polarisation (ca. $4 \mu C/cm^2$) out of the $a-b$ plane, with the majority of the polarisation (ca. $50 \mu C/cm^2$) being in the plane, so that the ferroelectric structure is monoclinic. The T_C is high ($675^\circ C$) and ceramics have been explored for use as high-temperature piezoelectrics. The problem with the compounds when used as ceramics is that the piezoelectric coefficients are rather small. Single crystals have been explored for optical light-valve applications but have not received widespread use because of the problems of growth. Thin films of $SrBi_2Ta_2O_9$ (SBT) are receiving considerable attention for applications in ferroelectric nonvolatile memories.

Other Oxide Ferroelectrics

There is a wide range of other oxide ferroelectric materials, although none have anywhere near the breadth of application of the oxygen octahedral ferroelectrics discussed above. There are two groups of phosphates (in which the phosphorous ions are tetrahedrally coordinated by oxygens) which have found applications in optical systems. The potassium dihydrogen phosphate (KDP) family was referred to above as an example of an order-disorder ferroelectric. KDP, and its deuterated analogue KD^*P , can be grown from aqueous solution as large, high-quality single crystals. These can be lapped and polished into plates which are used for longitudinal electro-optic modulators, in which the modulating electric field is applied parallel to the direction of light propagation in the crystal. In this application, the crystals are used at room temperature in the paraelectric phase. One spectacular application for these crystals is as the Q-switches in the large ultra-high-power lasers used for nuclear fusion research, where extremely large (ca. 1 m) crystal slices are needed. Another class of phosphate ferroelectrics is the potassium titanyl phosphate system (KTP). These crystals can be grown relatively easily from the melt and are used for optical frequency doubling applications, particularly using periodically poled crystals [27.17, 18]. This is a large family in which the potassium can be replaced by caesium or rubidium and the phosphorous by arsenic. Lasers using KTP are finding significant uses in surgical procedures [27.19].

Fig. 27.11 Schematic diagram of half of the unit cell of the crystal structure of an Aurivillius compound with $m = 3$. The cell axes shown are those corresponding to the tetragonal structure

There are other examples of oxygen tetrahedral ferroelectrics. Lead germanate ($\text{Pb}_5\text{Ge}_3\text{O}_{11}$) is an interesting material which has been prepared as a single crystal. It is a hexagonal uniaxial ferroelectric which is also optically active. Ge can be substituted up to 50% by Si, which reduces the Curie temperature from 177°C to 60°C . The sense of the optical rotation switches with the sign of the spontaneous polarisation. This has been considered for optical devices and pyroelectric infra-red detectors, but has not reached any commercial applications. It has been prepared in ceramic and thin-film form and is occasionally used as a sintering aid in lead-containing ferroelectric ceramics. Gadolinium molybdate, $\text{Gd}_2(\text{MoO}_4)_3$ (GMO), possesses a structure consisting of corner-linked MoO_4 tetrahedra. It is an example of an improper ferroelectric material in which the phase transition from the paraelectric phase is controlled by the softening of a zone boundary mode, which would lead to a nonpolar low-temperature phase, which is in fact *ferroelastic*. The high-temperature phase is acentric, and the ferroelastic lattice distortion couples via the piezoelectric coefficients to give a spontaneous polarisation. The lattice distortion can be reversed by electrically switching the spontaneous polarisation and vice versa. GMO has no commercial applications, although it was at one time considered for optical switches.

27.1.2 Triglycine Sulphate (TGS)

The TGS family is a salt of the simplest amino acid, glycine ($\text{NH}_2\text{CH}_2\text{COOH}$) with sulphuric acid. In the crystal structure, the glycine groups are almost planar and pairs of them are connected by hydrogen bonds. A ferroelectric transition at 49.4°C between two monoclinic phases is driven by an ordering of the protons in these hydrogen bonds. The replacement of these protons by deuterons (which can be accomplished by repeated crystallisation of TGS from heavy water) to give DTGS results in a 10°C increase in T_C . There has been a great deal of academic interest in TGS because it possesses a well-behaved second-order order-disorder ferroelectric phase transition. In addition it has been of considerable technological interest for uncooled pyroelectric infra-red detectors and thermal imaging devices [27.20]. As a consequence, there has been considerable work on the replacement of various components with the objective of either improving performance or increasing T_C , such as can be achieved by deuteration. The replacement of glycine by l-alanine has been demonstrated to result in an internal bias field in the

crystal, which means that the crystals will retain their single-domain structure, even if heated well above T_C .

27.1.3 Polymeric Ferroelectrics

The first polymeric ferroelectric to be discovered was polyvinylidene fluoride (PVDF). The monomer for this possesses the formula CH_2CF_2 . It was first shown to be piezoelectric by Kawai [27.21] and later Bergman et al. [27.22] speculated about the possibility of it being ferroelectric, although no Curie temperature could be shown to exist, as the polymer melts first. The structure of the polymer is complex, as the polymer backbone can adopt a number of configurations depending upon whether the neighbouring carbon-carbon linkages adopt trans or gauche configurations. In a trans (T) configuration, the groups bonded to the carbon atoms sit on opposite sides of the carbon-carbon bond. In a gauche (G) configuration, they sit on the same side. In an all-trans configuration, the carbon backbone of the polymer forms a simple zigzag. In the case of PVDF, there are four different phases with different T and G sequences, and with different ways the polymers stack together in crystal structures. The polymer crystallises from the melt into *form II*, also called the α -phase, in which the bonds arrange themselves into the sequence TGT $\bar{\text{G}}$, see Fig. 27.12. The fluorine atoms are strongly electronegative which makes the C–F bond polar so

Fig. 27.12 PVDF bond structures

that the molecule has a net dipole moment perpendicular to its length. However, the molecules of polymer arrange themselves in the unit cell so that the dipoles cancel each other out. Form II is neither ferroelectric nor piezoelectric, but application of an electric field will convert it into form II_p, also called the δ -phase, in which the polymer molecules are arranged so that the unit cell has a net dipole moment. High-temperature annealing of either of these forms will produce form III (the γ -phase), which has a new TGT $\overline{\text{T}}$ TGTT configuration which also has a net dipole moment perpendicular to the long axis of the molecule and these arrange in a crystal structure which is also polar. Subjecting forms II or III to stretching or drawing will produce form I (the β -phase), which is an all-trans configuration (Fig. 27.12). It can be seen from Fig. 27.12 that of the three molecular configurations, the polar bonds all point most-nearly in the same direction and this is retained in the unit cell. Electrical poling makes this the most-strongly piezoelectric phase of PVDF. The stretching can be in a single direction, called uniaxial and usually achieved by drawing through rollers, or in two perpendicular directions, called biaxial and usually achieved

by inflating a tube of polymer. Strong electric fields are needed for poling and these are frequently applied by placing the polymer under a corona discharge. The formation of a copolymer of vinylidene fluoride with between 10% and 46% trifluoroethylene (TrFE) leads to a polymer which will crystallise directly into form I (the β -phase) from either melt or solution. This can be poled to produce a material which is as active as pure PVDF. The copolymers also show clear signs of a ferroelectric-to-paraelectric transition, such as exhibiting peaks in permittivity at T_C , with a T_C that depends on the amount of TrFE in the copolymer. Extrapolation to 0% TrFE implies a T_C in PVDF of 196 °C. PVDF is readily available and has achieved moderately widespread use as a piezoelectric sensor material. It is particularly useful where light weight and flexibility are important, or where very large areas or long lengths are needed. The P(VDF-TrFE) copolymers are not as readily available and are not widely used. Other polymers that have been shown to exhibit ferroelectric behaviour include the odd-numbered nylons, but these are only weakly piezoelectric and have not achieved any technological uses.

27.2 Ferroelectric Materials Fabrication Technology

Ferroelectrics are used commercially in a very wide range of forms, from single crystals through polycrystalline ceramics and thin films to polymers. Hence, only a summary of the fabrication techniques can be presented here.

27.2.1 Single Crystals

As has been shown above, ferroelectrics often have a wide range of complex compositions. This renders the problems of single-crystal growth much more difficult than for single-element crystals such as silicon. In many cases, the most technologically useful compositions are themselves solid solutions of complex ferroelectric end members. Frequently these do not melt congruently and sometimes one or more components of the melt will be volatile. Some of the growth techniques which are used are:

Czochralski Growth

Certain ferroelectric crystals melt congruently and can be pulled from the melt using the Czochralski technique. Examples include LiNbO₃ and LiTaO₃. Both materials are widely used technologically. LiNbO₃ is

used in surface acoustic wave (SAW) and electro-optic devices and LiTaO₃ in pyroelectric infrared detectors, piezoelectric resonators, SAW and electro-optic devices. LiNbO₃ melts congruently at 1240 °C, but the congruently melting composition is not at the stoichiometric composition (Li : Ta = 1), but lies at around 49% Li₂O. Crystals pulled from such melts in platinum crucibles are perfectly adequate for piezoelectric and most optical applications. However, it is known that the stoichiometric composition possesses rather better optical properties than the congruent composition and there is now a premium-grade material available commercially. LiTaO₃ melts congruently at 1650 °C. Again, the composition is not at Li : Ta = 1, but is slightly Ta deficient. The growth temperature is above the melting point for platinum. The solution is to use crucibles made from iridium, which is very expensive. Also, IrO₂ is volatile so the growth atmosphere must be N₂, which means that the crystals come out of the melt oxygen-deficient and must be embedded in LiTaO₃ powder and annealed under O₂ after growth to make them clear. Pt/Rh crucibles have been used to grow LiTaO₃ crystals, but the Rh absorbed into the crystals makes them brown. Such crystals are acceptable for piezoelectric and pyroelectric, but not

for optical, applications. Virtually all ferroelectric materials need to be electrically poled before use. In the case of LiTaO_3 , silver electrodes are applied to faces perpendicular to the polar (c) axis and a pulsed field of about 10 V/cm (1 ms with a 50/50 duty cycle) applied while the crystal is cooled slowly through T_C (620 °C). A similar process can be applied to pole LiNbO_3 crystals, or as the T_C is very close to the growth temperature, the field can be applied between the growing crystal and the crucible. This process has also been used to grow periodically poled crystals in which the field is reversed periodically during the growth of the crystal. Such crystals have some advantages in optical frequency-doubling in a process known as quasi-phase matching [27.23].

Solution and Flux Growth

The growth of crystals from aqueous solution is a technology very readily applied to water-soluble materials such as KDP and TGS. There are two processes that have been used. The first consists of rotating crystal seeds in a bath of saturated solution, which is slowly cooled so that material that comes out of solution is deposited on the seeds. The second consists of recirculating the bath solution over feed material, which is held at a slightly higher temperature and then back over the slightly cooler seeds, where the feed material is deposited. In both techniques, very careful control of temperature is essential (better than 0.002 °C) and the growth process can take many days.

The process of growing oxide single crystals from solution or flux is closely related to the above process, in that the crystals are grown from a saturated solution of the required oxide in a molten flux as it is slowly cooled. In the simplest version of this process, the oxides are sealed in a platinum crucible, heated to a *soak* temperature and slowly cooled to room temperature. Small crystals (usually up to a few mm in size) can then be recovered from the solidified melt. This has been applied to growth of a wide variety of small single crystals, such as PZT and PMN-PT solid solutions. PZT, for example, can be grown from $\text{PbO}-\text{B}_2\text{O}_3$ flux mixtures, or even pure PbO [27.25]. BaTiO_3 crystals can be grown from KF or TiO_2 fluxes. A major issue with the growth of Pb-containing ferroelectrics from PbO rich fluxes is the evaporation of PbO from the melt at the crystallisation temperature over the long time periods required to grow large crystals. This can be avoided to some degree by the use of sealed crucibles. A variation on the flux growth process is top-seeded solution growth, whereby a seed crystal is immersed from above into a supersaturated solution of the material to be grown. The crystal then grows

Fig. 27.13 A modified Bridgman apparatus used for growing piezoelectric single crystals (after [27.24])

as the solution is cooled further. The process is difficult to control and it has the major problem, especially when growing from a PbO flux, that the melt is open and therefore very prone to flux evaporation. It has been successfully applied to the growth of crystals of PMN-PT and PZN-PT solid solutions. The Bridgman process seeks to get over this problem by placing a dense compact of the flux/solute mixture inside a sealed crucible with a conical end, as shown in Fig. 27.13. A seed crystal is placed at the base of the cone which is held cooler than the rest of the crucible by a cooled rod. A molten zone is then allowed to travel up the crucible and the crystal solidifies inside it. Good-quality crystals have been grown this way and it is the preferred technique for the manufacture of PMN-PT and PZN-PT solid solutions. One problem with all flux-growth techniques is that the flux composition is constantly changing during the growth process and therefore the crystals tend to be nonuniform in composition. This is a particular problem for larger crystals, especially for solid solutions.

27.2.2 Ceramics

The vast majority of ferroelectric materials that are used commercially are used in the form of polycrystalline

ceramics. These are used in many of the applications listed above, including as dielectrics and in piezoelectric, pyroelectric, PTCR and electro-optic devices. Many different ferroelectric ceramic fabrication technologies have been developed over the years, but they are all based around a similar fabrication sequence. The key points are discussed below. Note that as the vast majority of commercially exploited ferroelectrics are oxides, the discussion will centre around these materials.

- **Raw-material selection:** the usual starting point for a ceramic fabrication sequence is the selection of the raw materials. For oxide ferroelectrics, the raw materials are usually oxides or carbonates, but occasionally other compounds (e.g. nitrates, citrates etc.) are used which will decompose when heated to form the oxides required. High purity (usually > 99.9% with respect to unwanted cations) is important for good reproducibility. Small quantities of dopants can have a major effect on the final electrical properties, as would be expected for any electronic material, but can also seriously affect the sintering characteristics and grain size of the final ceramic body. Note that high purity does not usually imply the kind of purity that would be needed for a semiconductor material. Indeed, ultra-high purity (> 99.99%) is often obtained by raw-material manufacturers by applying processes which seriously affect the reactivity of the oxide powders. A high degree of solid-state reactivity in the powders is important for the processes which follow. This is usually determined by a combination of raw-material particle size and specific surface area, although selecting the right crystallographic phase can be important. When using TiO₂, for example, it is usually found that the anatase phase is more reactive than rutile. These factors can be analysed for quality control purposes by using laser particle size analysis (taking care to break up loosely bound agglomerates by ultrasonic dispersion in water, with a dispersing agent prior to measurement), BET (Brunauer, Emmett and Teller)-specific gas absorption and X-ray powder diffraction respectively. The majority of ceramics are made by mixing together powdered raw materials, but occasionally solution mixing techniques are used and these will be discussed further below.
- **Raw-material mixing:** this is usually done in a ball mill consisting of a cylinder containing a mixture of small balls or cylinders made of steel, steatite, zircon or yttria-stabilised zirconia (YSZ). The oxide raw materials are accurately weighed into the ball mill,

together with a predetermined amount of a milling fluid (usually deionised water, but occasionally an organic fluid such as acetone). It is usual to add a dispersant to aid the breakup of agglomerates. The ball mill is then sealed and rotated to mix the ingredients. Precise milling conditions are determined by the materials being used, but the mixing time is usually of the order of a few hours. It is advantageous to use milling balls that are made of a material whose wear products will be reasonably innocuous in the final ceramic. For this reason, YSZ balls are preferred, as small amounts of iron and silica contaminants can have unwanted or deleterious effects on the properties of many ferroelectric ceramics. For similar reasons, the ball mills are frequently rubber lined. Many variations on this process have been explored. High-energy ball milling is receiving considerable attention. In this process, the milling balls are given very high energy by either aggressively vibrating the ball mill or by stirring them at high speed with a paddle. Raw materials trapped between the balls are both comminuted and, if the energy is sufficiently high, can be forced to react together. Crystalline raw materials can be made amorphous in this process. A significant amount of energy can be stored in the powders after this process so that subsequent sintering can be undertaken at lower temperatures. In an adaptation of this process, it can be done in a continuous flow-through mill, whereby the slurry is pumped through the high-energy mill, making it less of a batch process.

- **Drying:** the slurry that results from the mixing process is dried after the milling balls are removed. On a small scale, this can be done in an oven, but on a commercial scale, this is usually achieved by spray drying.
- **Calcination:** the purpose of this process is to react the raw materials into the required crystallographic phase. The dried powders are placed into a sealed crucible (usually high-purity alumina or zirconia), which is baked in a furnace at a temperature high enough to decompose any non-oxide precursors and cause a solid-state reaction between the raw materials, but not so high as to sinter the particles and form hard agglomerates that will be difficult to break up in subsequent processing. A simple example is the reaction between BaCO₃ and TiO₂ to form BaTiO₃:

This reaction will go to completion at about 600 °C. Note that a much higher temperature (> 1000 °C) is

required for the decomposition of BaCO_3 to BaO in the absence of TiO_2 .

- **Milling:** this is usually done in a similar manner to the mixing process described above, but is done for longer. The objective is to break up hard agglomerates and reduce the powder to its primary particle size. Again, high-energy milling techniques can be used. Dispersants are usually added to aid the process, and pH is controlled so that the powder does not flocculate. Organic binders can be added at this stage. The slurry from the milling process is usually spray-dried or freeze-dried as a free-flowing aggregated powder is required. The objective is to form soft aggregates that will break up on subsequent die pressing. Alternatively, the slurry (or *slip*) can be taken straight to a slip- or tape-casting process.
- **Shape forming:** after drying, the powders from the above process can be uniaxially pressed into the *green* shape required, typically using a steel punch and die-set. It is important in this process to make sure that the force is applied equally to top and bottom punches. Usually, the die is designed with a slight taper to ease removal of the workpiece after pressing. Faults that can occur at this stage of the process include *capping* or radial cracks in the work piece, which usually result from an uneven distribution of pressure. One way to avoid this is to use cold isostatic pressing. In this process the powder, or more frequently a lightly uniaxially cold-pressed green block, is vacuum-sealed into a rubber mould, which is then immersed in a bath of oil. The oil is taken up to a high pressure, which isostatically compresses the block. The advantage of using this process is that it avoids the nonuniform distribution of pressure that is frequently a problem with uniaxially cold pressing. The high pressure allows the agglomerates to be broken up and the process usually results in a much higher green density, which facilitates the sintering process. Another process that can be used to form the green item is slip-casting, which involves pouring the ceramic slip into a plaster mould, which is usually gently rotated. The plaster absorbs moisture from the slip and the ceramic particles are deposited as a layer. Surplus slip is poured off and the deposited layer can be separated from the mould after it is dry. This process has been used to make large cylinders of piezoelectric ceramics. A third process that is frequently used to make thin sheets of ceramic is tape-casting, by which the slip is passed under a set of *doctor blades* in the apparatus shown schemati-

Fig. 27.14 Tape-casting apparatus

cally in Fig. 27.14. In this case, the slip is cast onto a continuous roll of plastic tape and a plastic binder is added to the slip which, when dry, holds the powder together and makes a flexible green tape. Sometimes the slip is cast directly onto a glass sheet. The green tapes can be screen-printed with patterns of metallic electrode inks and then laminated by warm-pressing to make multilayer structures with interleaved electrodes. This type of fabrication is widely used for multilayer ceramic (MLC) capacitors and multilayer ceramic piezoelectric actuators.

- **Sintering:** the green ceramic bodies are sintered in furnaces at temperatures of 1150–1300 °C, depending on the ceramic being manufactured. There is a good deal of process know-how in the sintering of the ceramic bodies. Key issues are:
 - The heating profile, which must be carefully controlled, especially over the lower range of temperatures up to about 500 °C where the organic matter (dispersants and binder) is burned off. Too rapid heating will cause large pores, or even cracks, to form.
 - For lead-containing ceramics, it is important that air be allowed free access to the vaporising organic material, or it will be carbonised and this can lead to reduction of the PbO in the ceramic to free Pb .
 - Loss of PbO by volatilisation at higher temperatures ($> \approx 800$ °C) means that the ceramic body needs to be sintered in a PbO -rich environment, which is often produced by packing the ceramic body in a *spacer powder* of PbZrO_3 , or **PZT** ceramic chips within well-sealed ceramic crucibles or saggars. This tends to restrict the access of air to the sintering ceramic body, which conflicts with the previous requirement.

- The ceramic body must be free to move during the sintering process, as there is significant linear shrinkage (about 15 to 18%). If the body is unable to slide over the surface on which it sits, this can lead to cracking, especially for large components. One solution to this problem is to sit the body on zirconia sand.

The sintering process has been very well described elsewhere. It is possible to obtain very high densities (> 98%) by careful control of the sintering conditions. For Pb-containing ferroelectric ceramics, a small excess of PbO is usually added to compensate for PbO loss by evaporation. This also tends to act as a liquid-phase-sintering aid, lubricating the grains of ceramic as they slide over each other in the sintering process, and providing a surface-tension force that pulls the ceramic grains together. The PbO also acts as a solvent, aiding the movement of the ceramic components during sintering and further densifying the ceramic. It is possible to sinter such materials to transparency, which means that there is virtually zero porosity. Very high densities can also be obtained by hot-pressing, in which the green body is placed inside a ceramic punch and die-set and raised to the sintering temperature under a pressure of about 35 MPa. Alternatively, hot isostatic pressing (HIP) can be used. In this process the pressure transmitting medium is a high-pressure gas (usually argon, but if the ceramic is Pb-containing it is important to include a few percent of oxygen to prevent reduction of the ceramic). In this case pressures of 100 MPa or more can be used. If the ceramic is pre-sintered so that there is no open porosity, then this can be achieved without the need for any container, but if there is open porosity, the body must be encapsulated in a suitable metal container, which will usually need to be a noble metal such as Pt.

- Electroding: good-quality electroding is essential for all ferroelectric devices for a variety of reasons. Any low-permittivity layer between the electrode and the ferroelectric material will manifest itself in a fall-off in capacitance and an increase in loss as the frequency of measurement is increased. Poor-quality electrodes, or even the wrong type of conductive material can lead to problems with device ageing, or even an inability for the device to function as intended. Most piezoelectric materials are supplied with a *fired-on* silver electrode, which is a mixture of silver powder, a finely divided glass frit and a fluxing agent. Obtaining the correct balance between metal and glass contents is important, as too high

a proportion of metal will lead to poor electrode adhesion while too high a proportion of glass will lead to poor electrode conductivity. Such electrodes are solderable with the use of appropriate fluxes. Sputtered or evaporated metal electrodes such as Ni or Cr/Au can also be used, as can metal electrodes deposited by electroless processes (e.g. Ni). The ohmic nature of the electrode contact to the ceramic is not usually important for highly insulating materials, such as piezoelectrics, but is important for semiconducting ceramics such as PTCR BaTiO₃. In this case it is usual to use Ni electrodes, which need to be annealed after deposition to develop the ohmic contact. In some cases it is necessary to fire on the electrode at the same time as ceramic sintering (cofired electrodes). This is particularly important where the electrodes are buried in the structure, as with MLC capacitors and actuators. Clearly, there are problems to solve here in terms of the potential oxidation or melting of the electrode material. The conventional materials to use in such electrodes have been noble metals such as palladium (sometimes alloyed with silver) or platinum, which are very expensive. There have been serious efforts to develop ferroelectric compositions that can be fired with base metal electrodes such as Ni. In the case of BaTiO₃-based dielectrics, this has entailed the development of heavily acceptor-doped compositions that can stand being fired in a neutral or slightly reducing atmosphere. In the case of MLC actuators, there has recently been some success in developing piezoelectric PZT compositions that can stand being fired in such atmospheres, using Cu as the electrode material.

- Poling: many devices made from ferroelectric ceramics (all piezoelectric and pyroelectric devices) require poling before they will develop useful properties. This entails applying a field that is significantly in excess of the coercive field (typically 3×), usually at an elevated temperature. It is not usually necessary to exceed the Curie temperature. For example, PZT ceramics with T_C in the range 230–350 °C can be poled by applying 35–kV/cm (depending on the type of PZT – see below – soft PZTs need lower poling fields than hard PZTs) at about 150 °C, with the field kept applied while the workpiece is cooled to room temperature. It is usual to immerse the ceramic in a heated bath of oil (mineral or silicone) during the process. One disadvantage of this is that the ceramic then needs to be carefully cleaned after poling. Silicone oil can

be very hard to remove completely and its presence as a residue will compromise electrode solderability. For this reason, some workers have developed a process whereby the ceramic is poled under SF_6 gas. There is a rapid decay of properties after poling. This decay stabilises after a few hours, so it usual to wait at least 24 hours before electrical properties are measured.

There are many variations on the above basic process route which have been researched. One of these is the use of solution techniques to prepare the oxide powders. The basic principle here is that if the cations are mixed in solution, then they will be mixed on the interatomic scale without the need for milling processes that can introduce impurities. (This is a matter of discussion, as the act of precipitation and decomposition can lead to separation of the components.) Many routes have been explored, including the use of inorganic precursors such as nitrates and metalorganic precursors such as oxalates, citrates or alkoxides and acetates. Some of these have achieved a degree of commercial success, although the use of solution routes is more complex and the raw materials much more expensive than the mixed oxide routes. The use of mixed barium titanium oxalates has been very successful in producing high-quality fine-grained barium titanate powder for use in the capacitor industry. The use of metal citrates (frequently called the Pechini process) has been successfully used on a research scale to prepare many different types of ferroelectric oxide, but this type of process has not been applied on a commercial scale. Metal alkoxides, such as titanium isopropoxide, are readily soluble in alcohols and will react quickly with water to precipitate a hydroxide gel. Workers have used mixtures of titanium and zirconium alkoxides with lead and lanthanum acetates to coprecipitate a mixed hydroxide gel that could be calcined and sintered to make transparent lead lanthanum zirconate titanate ceramics for electro-optical applications.

27.2.3 Thick Films

There has been considerable interest in the integration of thick (10–50 μm thick) films of ferroelectric materials with alumina and other types of substrates such as silicon, to complement the wide range of other thick-film processes that are available, covering conductors, dielectrics, magnetic materials etc. There are many potential advantages to thick film processing for making certain types of sensor, especially the ability to use screen-printing for depositing the patterns of the ma-

terials required. Screen-printing involves using a sheet of wire mesh (the *screen*) that is coated with a photosensitive polymer. Exposure and development of the polymer allows selected areas to be removed, opening regions through which a paste of the required material can be pushed using a rubber blade or squeegee. The principle is simple, but there is a considerable amount of know-how in the formulation of the paste, which consists of the active material (in this case a ferroelectric powder such as PZT), an organic vehicle (a mixture of a solvent and polymer) and a glass frit. The screen is stretched over a former, and held close to, but not in contact with, the surface onto which the print is required. The paste is placed on the screen, and then spread over the screen with the squeegee, which prints the paste onto the substrate. Successive layers of different materials can be printed and cofired, provided there is good compatibility between them. The process has been well developed for piezoelectric films and adequate properties have been obtained from the films, although they are still well below the values that could be expected from a bulk ceramic material. (See review by Dorey and Whatmore [27.26] for further details.)

27.2.4 Thin Films

The integration of high-quality thin films ($< 0.1\text{--}5\ \mu\text{m}$ thick) of ferroelectric materials onto substrates such as silicon has excited considerable interest for potential applications ranging from nonvolatile information storage to their use as active materials in micro-electro-mechanical systems (MEMS), where they can potentially be used for microsensors and actuators. Almost all the interest has been in the use of oxide ferroelectrics, but there has been some interest in the use of P(VDF-TrFE) copolymer films. These can be spun onto electroded substrates from methyl ethyl ketone solution. They are dried at relatively low temperatures ($< 100\ ^\circ\text{C}$) and crystallised by annealing at $180\ ^\circ\text{C}$ for several hours [27.27]. Such films have been applied to pyroelectric devices. However, the activity coefficients which can be obtained from such films are much lower than those that can be obtained from oxide materials. A range of deposition techniques have been developed for growing ferroelectric oxide films, which are summarised below:

- Chemical solution deposition (CSD): this term is applied to a wide range of processes that involve taking the metal ions into metalorganic solution, which is then deposited on the substrate by spinning, fol-

lowed by drying and annealing processes to remove the volatile and organic components and convert the layer into a crystalline oxide. There are two broad classes of CSD process: metalorganic deposition (MOD) and sol gel. The MOD processes usually involve dissolving metal complexes with long-chain carboxylic acids in relatively heavy solvents such as toluene. The carbon content of the precursors is quite high, so there is a good deal of thickness shrinkage during firing. MOD solutions tend to be quite stable with time and resistant to hydrolysis. Sol-gel processes use precursors such as metal alkoxides, acetates and β -diketonates in alcohol solution. (For example, a set of precursors to deposit PZT would be Ti isopropoxide, Zr n-propoxide and lead acetate). Alkoxide precursors are very susceptible to hydrolysis, and so careful control of moisture content during the sol synthesis is essential and stabilisers such as ethylene glycol are usually added to the solutions to extend the useable lifetimes of the sols. Whereas MOD solutions are true solutions, the sols are actually stable dispersions of metal oxide/organic ligand particles with a size of about 4–6 nm. Sols possess lower viscosities and tend to produce the oxide layer at a somewhat lower temperature than the MOD processes, but the individual layer thicknesses produced by a single spin tend to be lower. Single crack-free layers tend to be in the range 100–200 nm thick. CSD processes have the advantages that they are low cost, the composition can be easily changed and they produce very smooth layers. The processes are planarising and will not follow underlying surface topology, which can be a disadvantage. Also, the processes are not industry standard in that they are wet and tend to have many variations.

- Metalorganic chemical vapour deposition (MOCVD): this is a variation on the process that has been very successfully applied to the growth of group III–V semiconductor layers. The principle is simple: volatile metalorganic compounds are passed over a heated substrate, where they decompose to form a layer of the desired compound. The problem with the growth of ferroelectric oxides is that most of the available metal organic precursors are relatively nonvolatile at room temperature. There has, therefore, been a great deal of research into the available precursors for the compounds that are required. Metal alkyls (such as lead tetraethyl) are very volatile, but only available for relatively few of the metal ions of interest (Pb being the main one). They are also pyrophoric and highly toxic.
- Some metal alkoxides, such as Ti isopropoxide, are suitable MOCVD precursors. Metal β -diketonates and related compounds such as tetramethyl heptanedionates (THDs) have received considerable attention as Ba and Sr precursors. All of these precursors need to be heated to give them suitable volatility and this means that the lines connecting the precursor source to the growth chamber need to be heated as well. Some of the precursors (especially THDs) are solids, which means that they are not really suitable for use in conventional bubbler-type sources. There has been considerable success in using solutions of these compounds in tetrahydrofuran (THF). The solutions are sprayed into a vaporiser that consists of a cylinder, containing wire wool or ball bearings, heated to a temperature at which the solution will flash-evaporate. A carrier gas is passed through the cylinder and this carries the precursor vapour into the growth chamber. The growth chamber is usually held at reduced pressure and a certain amount of oxygen is introduced to aid the oxide deposition. Frequently a radio-frequency (RF) or microwave plasma is also introduced to aid the growth of a high density film and reduce the required substrate temperature. The major problem with the MOCVD process for complex ferroelectric oxides which have many cation components is finding the right combination of precursors that will all decompose at the same substrate temperature (usually ca. 550–650 °C) at a rate that will give the desired composition in the film. The process has been very successful in growing thin films of materials such as (Ba, Sr)TiO₃, with potential applications in the dynamic random-access memory (DRAM). The major advantage of MOCVD is that it is a truly conformal growth technique, with major advantages for semiconductor devices with complex topologies, but is a very expensive technique to set up because of the complex growth and control systems needed. Also, precursor availability is still a problem for many systems.
- Sputtering: a range of sputtering processes have been applied to the growth of ferroelectric thin films, including RF magnetron sputtering, direct-current (DC) sputtering and dual ion-beam sputtering. The RF magnetron process is probably the most popular. With all the processes, the major problem is one of obtaining the correct balance of cations in the growing film. Many different solutions have been found to this problem. In reactive sputtering, a composite metal target can be used. This can be made of segments of the metals to be sputtered (for exam-

ple, Pb, Zr and Ti for PZT) and their relative areas changed to obtain the right composition in the film. Alternatively, multiple targets can be used and the substrate exposed to each one for different lengths of time, or the power applied to each one can be varied. In reactive sputtering, it is necessary to have an amount of oxygen in the sputtering gas (usually Ar). It is possible to sputter ferroelectric thin films from ceramic or mixed powder targets, but it is necessary to adjust the target composition to allow for different yields for each element. In any sputtering process there are many variables to adjust to optimise the process, including the sputtering power, and RF or DC substrate bias, which will affect the ion bombardment of the growing film, the sputtering atmosphere pressure and gas mixture and the substrate temperature. All of these can affect the film growth rate, composition, crystallite size and crystalline phases that are deposited, and the stress in the growing film. For this reason, the development of a sputtering process for a complex ferroelectric oxide can be a time-consuming business, and once a set of conditions has been arrived at for one particular composition, it cannot quickly be changed to accommodate new compositions. Dual ion-beam sputtering differs from the RF and DC processes in that a much lower background pressure is used, the material is sputtered from the target using an ion beam and a second lower-energy ion beam is used to stimulate and densify the growing film. The sputtering processes have the advantage of being well accepted industrially, as they are dry and can readily coat large-area substrates.

- Laser ablation: this process involves bombarding a ceramic target with a pulsed, focussed laser beam, usually from an ArF excimer source. The target is held under vacuum. A plasma plume is produced and the products ablated from the target are allowed to fall on a heated substrate. The advantages of the process are that there is usually good correspondence between the composition of the target and the growing film. Relatively small ceramic targets are acceptable for the process, and it is thus a good method for getting a rapid assessment of the properties of thin films of a given material. The disadvantages of the process are that the plasma plume will only coat a relatively small area of substrate, although there are now systems which use substrate translation to coat large areas, and particles can be ablated from the target, causing defects in the growing film.

In all the techniques used for the growth of ferroelectric oxide thin films, the key issues are control of composition and the formation of the desired crystalline phase (usually perovskite) with the desired crystallinity (crystallite size, morphology and orientation). All of the ferroelectric perovskites have a tendency to crystallise into a non-ferroelectric fluorite-like pyrochlore phase at low temperatures. In the case of the CSD processes, this means that as the film is heated from room temperature, after it loses the organic components, it first forms an amorphous oxide which then crystallises into a nanocrystalline pyrochlore phase, finally forming the desired perovskite phase. The temperatures at which this will occur depend very much on the ferroelectric oxide that is being grown and the precise composition. In the case of PZT, the pyrochlore phase will form above about 300–350 °C. The perovskite phase will start to form above about 420 °C, depending upon the ratio of Zr : Ti in the solid solution. The compositions close to PbTiO₃ will crystallise into perovskite much more readily than those close to PbZrO₃. In the case of a complex perovskite, such as Pb(Mg_{1/3}Nb_{2/3})O₃ or PbSc_{1/2}Ta_{1/2}O₃, the pyrochlore phase is much more stable and much higher temperatures (> 550 °C) are needed to convert it to perovskite. Excesses of PbO will tend to favour the formation of perovskite, and deficiencies favour pyrochlore. Higher annealing temperatures will promote PbO loss and it is possible to get into a position, through PbO loss, where the pyrochlore becomes the most stable phase, even at high annealing temperatures. Residual pyrochlore phase invariably compromises the electrical properties of the films through reduced permittivity and piezoelectric/pyroelectric coefficients. The other growth techniques have the advantage that the films can be deposited onto heated substrates, at temperatures where they will grow directly into the perovskite phase (at least in principle), although there are many examples in the literature of films being deposited (e.g. by sputtering) at low substrate temperatures and converted to the desired perovskite phase by post-deposition annealing, in which case the same problems of pyrochlore formation apply. The control of film crystallinity (crystallite orientation and size) is important as it has a direct effect on the electrical properties. This is usually achieved through control of the crystallite nucleation. Sputtered Pt is frequently used as a substrate onto which ferroelectric thin films are grown. Like many metals, this will naturally grow with a (111) preferred orientation. It is face-centred cubic (FCC), with a lattice parameter of about 3.92 Å, which matches the lattice parameters of many of the ferroelectric perovskites, which are about

4 Å. This means that, with appropriate process control, it is quite possible to get a highly orientated (111) ferroelectric film on Pt, with a crystallite size of about 100 nm. Changing the underlying nucleation layer can allow other orientations to be grown. For example, the use of thin films of TiO₂ or PbO on top of the Pt electrode can induce a (100) orientation. It is important to

control the nucleation density of the perovskite phase. If this is allowed to become too low, than large circular grains several microns in diameter (called *rosettes*) can form, which tend to induce defects at their boundaries. (Further details on thin-film ferroelectric growth techniques can be found in the book by *Pas de Araujo* et al. [27.28]).

27.3 Ferroelectric Applications

27.3.1 Dielectrics

As noted above, BaTiO₃ possesses a very high permittivity close to T_C . The inclusion of selected dopants can reduce T_C and optimise the properties of the material for capacitor applications. The substitution of Sr²⁺ for Ba²⁺, for example, will reduce it, so that at about 15% substitution it will occur at about 20 °C. Substitution of Zr⁴⁺ for Ti⁴⁺ has a similar effect. The use of off-valent substitutions will have an effect upon resistivity and degradation characteristics, so that substituting La³⁺ on the A site will reduce resistivity at low concentrations. Substituting Nb⁵⁺ on the B site at the 5% level has been shown to confer resistance to degradation. The addition of Mn to the lattice has been shown to have a positive effect on dielectric loss. Control of grain size has also been shown to have a marked effect on dielectric properties. Reducing the grain size has the effect of increasing the concentration of domain walls per unit volume of ceramic, and thus increasing the domain-wall contribution to the permittivity. A reduction in grain size also brings about an increase in the unrelieved stress on the grains, which further increases the permittivity. Once the grain size falls below about 0.5 µm, the stress on the grains reduces their tetragonality and the permittivity falls. It is also possible to use heterogeneity in the ceramic grains to flatten the curve of dielectric constant versus temperature. A range of Electronic Industries Alliance (EIA) codes have been introduced to define the variation of capacitance with temperature. The X7 temperature range, for example, is −55–+125 °C, while following this with the letter R would specify a capacitance change of no more than ±15%. Other dielectrics have been developed based on PMN that have higher peak permittivities, but worse temperature characteristics, capable of meeting a Z5U specification (+22 to −56% capacitance variation over the range 10–85 °C) but not much better. There has been huge progress in MLC technology, with capacitors now available with

> 100 layers of submicron thickness and capacitances ranging from a few hundred pF to 100 µF. The majority of these now have base-metal (Ni) electrodes. The fabrication of the ceramic dielectrics for these is a very complex area and a great deal of technology has been developed to service a very large MLC capacitor market (615 Bn units in 2002, worth an estimated \$ 8.4 Bn).

27.3.2 Computer Memories

The storage of digital information is of great interest and growing technological importance. The ability of ferroelectrics to store information via the sense of the spontaneous polarisation has made them candidates for this application ever since the advent of the electronic computer. However, it is only with the development of the techniques for the growth of ferroelectric thin films onto silicon at relatively low temperatures (see above) that their use has become a reality. There are two ways in which ferroelectrics can be used in computer memories. The first is the replacement of the dielectric layer in dynamic random-access memories (DRAMs). Here, the motivation is to exploit the high permittivities exhibited by ferroelectric oxides to reduce the area of silicon required to store a single bit of information. The favoured materials here are based on (Ba, Sr)TiO₃, while the favoured technique for thin-film growth is plasma-enhanced MOCVD because of its ability to deposit conformal coatings. No DRAM devices using these thin films have yet reached the market place. The use of the switchable polarisation for the nonvolatile storage of information has received a great deal of research. A good deal of this work has been based upon the use of PZT thin films, grown by a variety of techniques, including CSD, RF sputtering and MOCVD. Initially, there were many problems to solve, including the decay of the switchable polarisation (ca. 35 µC/cm²) as the number of switching cycles increased (fatigue), the tendency for the polarisation in a bit to become less easily switched with time

and the number of times it is switched in the same sense (imprint) and the tendency for the switchable polarisation in any one bit to decay with time (retention). The fatigue and imprint problems in **PZT** have been ascribed to the motion of oxygen vacancies addressed by the use of oxide, rather than metallic, electrodes and doping to reduce the vacancy concentration. It has also been demonstrated that aurivillius compounds such as strontium bismuth tantalate (SBT) and La-doped $\text{Bi}_4\text{Ti}_3\text{O}_{12}$ not show fatigue behaviour, although they do require rather higher growth temperatures than the **PZT** family and have a significantly smaller switchable polarisation (ca. $7 \mu\text{C}/\text{cm}^2$). A number of companies are now making chips with nonvolatile on-board embedded ferroelectric random-access memory (FRAM). These are going into applications such as smart cards and computer games.

27.3.3 Piezoelectrics

This represents the most diverse range of applications for ferroelectric materials, as noted in the introductory section, covering a wide range of sensors, actuators and acoustic wave components for frequency control and filtering applications. The key properties determining the performance of a piezoelectric material in a particular application are the piezoelectric coefficients, elastic and dielectric constants. These are all tensor properties (see Nye [27.29]) and are combined through the constitutive equations:

$$D_i = d_{ijk} X_{jk} + \varepsilon_{il} E_l,$$

$$x_{ij} = s_{ijkl}^E X_{kl} + d_{mij} E_m,$$

where D_i = electric displacement, E_i = electric field, X_{ij} = stress, x_{ij} = strain, d_{ijk} = piezoelectric coefficients, ε_{ij}^X = dielectric permittivity coefficients at constant stress, and s_{ijkl}^E = elastic compliance coefficients at constant electric field.

The above equations use the Einstein repeated-suffix tensor notation. Note that most piezoelectric equations use the reduced-suffix notation for the piezoelectric and elastic constants [27.29].

There are two basic modes of operation for piezoelectric sensors and actuators. The first is well away from any mechanical resonance – usually at low frequency or quasi-DC. Here, the electric signals generated by an applied stress, or the strain generated by an applied electric field can be easily calculated using the constitutive equations of the type quoted above. The commonly used modes for operating piezoelectric ceramic actuators are longitudinal, where the electric field is applied

Fig. 27.15 (a) Piezoelectric bimorph and (b) MLC actuator structures

parallel to the direction in which strain is required and the coupling is via the piezoelectric d_{33} coefficient, and transverse, where a field is applied along the polar axis, but the exploited strain is perpendicular to this direction and coupling is via the d_{31} and d_{32} coefficients. Corresponding modes are frequently used for piezoelectric sensors. The two most commonly used actuator structures are illustrated in Fig. 27.15. Figure 27.15a shows a piezoelectric bimorph, in which two pieces of piezoelectric ceramic are bonded to a central metal shim. Fields are applied parallel to the polar axes of the ceramic elements so that their transverse extensions are equal and opposite. Usually one end of the bimorph is clamped so that the other end bends. In a variation on this structure, a single piece of ceramic is bonded to a piece of metal, making a unimorph. Bimorph and unimorph devices can provide high displacements (several tens to thousands of microns at up to 200-V drive) but relatively low forces (typically up to 1 N), depending on the size of the bimorph. The second widely used actuator structure is the multilayer ceramic actuator (Fig. 27.15b). This device operates in longitudinal mode, with applied field and extension parallel to the polar axis. The division of the structure into many thin layers reduces the voltage required to obtain a given extension. Typical devices can produce a few to a few tens of microns extension at a few hundred Volts (depending on dimensions) but high forces (in the kiloNewtons range). It is also possible to use a shear mode of operation for both sensing and actuation. In this actuation mode, the field is applied perpendicular to the polar axis and a shear strain is generated in the plane containing the vectors parallel to the applied field and the polar axis.

Many piezoelectric devices are operated under an alternating electric field whose frequency is tuned to match a mechanical resonance. A piezoelectric element oper-

Fig. 27.16 (a) Piezoelectric element equivalent circuit (b) Admittance versus frequency for a typical piezoelectric resonator

ated well away from resonance will exhibit a capacitive impedance characteristic. As a mechanical resonance is approached, the electrical behaviour of the element can be characterised using an equivalent circuit as shown in Fig. 27.16a. C_0 is the static capacitance. The L_m , R_m , and C_m form the motional arm of the circuit. If the admittance of such a circuit is plotted as a function of frequency, a behaviour is obtained as shown in Fig. 27.16b. The maximum in the admittance is very close to the mechanical resonant frequency (f_r), while the minimum in the admittance is close to antiresonance (f_a); f_r is determined by the elastic properties of the piezoelectric, its density and the dimensions relevant to the particular resonant mode. It is useful to define an effective electromechanical coupling coefficient k_{eff} which is defined by:

$$k_{\text{eff}}^2 = \frac{\text{mechanical energy converted to electrical energy}}{\text{input mechanical energy}}$$

or

$$k_{\text{eff}}^2 = \frac{\text{electrical energy converted to mechanical energy}}{\text{input electrical energy}}$$

k_{eff} can be determined from f_r and f_a :

$$k_{\text{eff}}^2 \approx \frac{f_a^2 - f_r^2}{f_a^2}$$

It can be shown that, for a simple resonant mode of a piezoelectric element, k_{eff} takes the form:

$$k_{\text{eff}}^2 = \frac{d^2}{s^E \epsilon^X}$$

where the d , s and ϵ coefficients in this equation are combinations of the piezoelectric, elastic and dielectric permittivity coefficients. The precise combination of the coefficients will depend on the shape of the piezoelectric element and the mode being excited into resonance. A list of the more commonly used modes and the dependence of k_{eff} on the relevant materials constants is given in Table 27.4. For more complex structures, such as those which involve a piezoelectric element (or elements) bonded to a metal component, it is still possible to define and measure a k_{eff} , but its value will be a much more complex combination of the materials constants, and will also involve the properties of the metal parts and the relative dimensions of the piezoelectric and metal components. (For more details refer to the IEEE standards on piezoelectricity).

By far the most widely exploited piezoelectric materials system is based on the $\text{PbZr}_x\text{Ti}_{1-x}\text{O}_3$ ceramic solid solution series. Most of the compositions of-interest are centred on the morphotropic phase boundary (MPB) region (Fig. 27.7) with $x = 0.52$. In the undoped series, the piezoelectric coefficients and dielectric constants peak at this composition. However, their properties can be greatly enhanced by the inclusion of selected cation dopants. These can be classified as follows:

- **Isovalent:** these are divalent cations that will substitute for Pb^{2+} on the A site (e.g. Sr^{2+}) or tetravalent ions (e.g. Sn^{4+}) substituting for Ti/Zr^{4+} on the B site.
- **Donors:** these are cations with a valency greater than the site onto which they substitute (e.g. La^{3+} for Pb^{2+} or Nb^{5+} for Ti/Zr^{4+}).
- **Acceptors:** these are cations with a valency lower than the site onto which they substitute (e.g. K^+ for Pb^{2+} or Ni^{3+} for Ti/Zr^{4+}).
- **Multivalent:** these are ions that take multiple valency (e.g. Mn substituted on the B site).

The broad effects of each class of dopants are listed in Table 27.5.

The resulting **PZT** ceramics are broadly classified into *hard* or *soft* according to whether they are doped with acceptors or donors, respectively. Each manufacturer has its own nomenclature scheme for its piezoceramic products. However, the US Navy produced a set of specifications under MIL-STD-1376B

Table 27.4 A list of the most commonly used piezoelectric resonances and the dependence of the k_{eff} for each on the piezoelectric, elastic and dielectric constants [27.30]

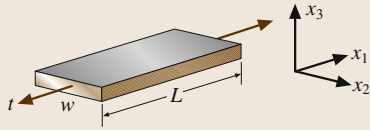

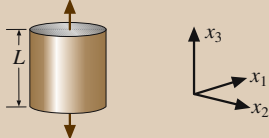

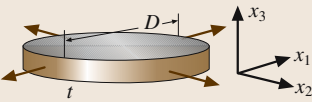

Mode type	Mode shape	Coupling factor
Length extensional mode of a bar using transverse excitation $L > 5w, L > 10t$		$k_{31}^l = d_{31} / \sqrt{\epsilon_{33}^T S_{11}^E}$
Length extensional mode of a cylindrical rod using longitudinal excitation $L > 10 \times \text{diameter}$		$k_{33}^l = d_{33} / \sqrt{\epsilon_{33}^T S_{33}^E}$
Radial mode of a round plate using longitudinal excitation $D > 20 \times \text{thickness}$		$k_p = k_{31} / \sqrt{2/(1-\sigma^p)}$
Grey areas denote the electroded surfaces		

Table 27.5 The effects of substituents in the PZT system (after [27.8])

Isovalent substituents e.g. Sr^{2+} for Pb^{2+} , Sn^{4+} for Zr^{4+}	Donor substituents e.g. La^{3+} for Pb^{2+} , Nb^{5+} for Zr/Ti^{4+}
<ul style="list-style-type: none"> Lower Curie point Increase permittivity Small improvement in linearity at high drive No change in coupling factor, aging, volume resistivity or low amplitude mechanical or dielectric loss 	<ul style="list-style-type: none"> No change in Curie point Higher permittivity Higher electromechanical coupling Poorer high drive linearity
	<ul style="list-style-type: none"> Lower aging Increase resistivity Reduced Q_E and Q_M
Acceptor substituents e.g. K^+ for Pb^{2+} ; Fe^{3+} for Zr/Ti^{4+}	Variable valence substituents e.g. Mn – can be 2+, 3+, 4+ – for Zr^{4+}
<ul style="list-style-type: none"> No change in Curie point Lower permittivity Lower electromechanical coupling Improved drive linearity Little change in aging Volume resistivity reduced Increased Q_E and Q_M 	<ul style="list-style-type: none"> No change in Curie point Range of permittivity Range of electromechanical coupling – usually lower High drive/linearity not changed Reduced aging

which are universally recognised. Hard ceramics (e.g. US Navy type III) have relative permittivities in the range of 1000 with high Q_s (> 500) and d_{33} of about 215 pC/N. Soft ceramics (e.g. US Navy type VI) have much higher permittivities (3250) and piezoelectric coefficients ($d_{33} = 575$ pC/N) but lower Q 's (65). Hard ceramics have much better drive-voltage stability and higher Curie temperatures than soft ceramics. The soft compositions tend to be

used for actuator applications, where the maximum piezoelectric displacement for a given drive voltage is sought, while soft ceramics tend to be used for resonant and sound-generation applications. There are, however, exceptions to this. Medical ultrasound transducer arrays tend to use soft, high-permittivity ceramics, because they need to have the maximum charge sensitivity in the reception of the sound waves reflected from tissues within the body, and

Table 27.6 Typical values for the piezoelectric, dielectric and elastic properties of some selected piezoelectric ceramic materials (taken from [27.31])

Material type	I	III	V	VI	Units
Stress-free relative permittivity (ϵ_{33})	1275	1025	2500	3250	
Dielectric loss tangent ($\tan \delta$)	≤ 0.006	≤ 0.004	≤ 0.025	≤ 0.025	
d_{33}	290	215	495	575	pC/N
k_p	0.58	0.50	0.63	0.64	
Mechanical quality factor Q_m	≥ 500	≥ 800	≥ 70	≥ 65	
Curie temperature (T_C)	325	325	240	180	°C

high permittivities because the small elements usually need to drive transmission lines with significant capacitance.

There are other types of piezoelectric ceramics that are used for specialist applications. Modified PbTiO₃ ceramics possess very low values of d_{31} and tend to be used for ultrasound array applications where small cross-coupling between adjacent elements is important. They also possess much higher response to hydrostatic stress than MPB PZT ceramics. Because of this, arrays of small blocks of this type of ceramic are used in flank array sensors in submarines. As noted above, lead metaniobate ceramics are used in high-temperature applications. Table 27.6 lists the piezoelectric and other properties of some selected piezoelectric ceramics.

Single crystals of PZN-PT and PMN-PT have received considerable attention because of the very high piezoelectric d_{33} coefficients and k_{33} coupling factors that can be obtained and single-crystal plates of these are now commercially available. Table 27.7 lists some of the properties that have been measured from these materials, and compares them with a commercial soft PZT ceramic.

Single crystals of LiNbO₃ are widely used in surface acoustic wave devices. In these, interdigitated electrodes (IDE) are applied to one polished face of a crystal. Excitation of these with an RF field will cause the generation of piezoelectrically excited Rayleigh waves, which will propagate with very little attenuation. These can be detected by further sets of IDE placed on the same face of the crystal. Such devices are widely used in signal processing and filtering applications in mobile telecommunication applications.

Thin films of piezoelectric materials, excited into thickness-mode resonance, are being explored for very-high-frequency (> 1 GHz) resonant filter applications.

27.3.4 Pyroelectrics

The pyroelectric effect is now widely used in uncooled detectors of long-wavelength infrared radiation (IR). The principle behind the operation of these devices is very simple. The radiation to be detected is allowed to fall upon a thin chip of the pyroelectric material. The energy absorbed causes a change in temperature and the generation of a pyroelectric charge, which will cause the flow of current in an external circuit. This can be amplified and used, for example, to switch an alarm. The basic circuit of a pyroelectric detector is shown schematically in Fig. 27.17. The field-effect transistor (FET) amplifier needs to be close to the pyroelectric element, ideally in the same package. This is because the latter has a very high output impedance and thus is very noise sensitive. The pyroelectric signal is represented in this circuit as a current source, i_p . i_p is proportional to the rate of change of the element temperature with time. Pyroelectric devices do not have a DC response. They only see changes in the intensity of the radiation with time. This is a major advantage in many applications, where usually there is a requirement to detect changes in the radiation coming from a scene, rather than the average or unchanging background intensity. An example of this is the requirement to detect the radiation from a person coming into the field of view of an IR detector.

Pyroelectric devices have several advantages over other radiation detectors. Their response is independent of the wavelength of the incident radiation, provided there is some means to absorb the radiation. Hence, pyroelectric radiation detectors have been used across the full range of the electromagnetic spectrum, from microwaves to X-rays. Basically a single pyroelectric detector design can be used for different wavelengths of radiation, simply by equipping the package with different windows coated with filters according to

Fig. 27.17 Schematic diagram of a pyroelectric IR sensor

the radiation it is desired to sense. Such devices are widely used in spectroscopic sensors for, e.g. automotive exhaust-gas analysis. However, by far the widest application of pyroelectric detectors is in the sensing of IR in the wavelength range 8–14 μm . The reasons for this are that there is an atmospheric window of low absorption and that objects with temperatures in the range of room temperature (300 K) emit most of their radiative energy in that waveband. However, all of the semiconductor detectors of 8–14 μm IR need to be cooled to about 77 K to work efficiently. On the other hand, pyroelectric detectors work perfectly well uncooled. Cheap detectors are readily available for under \$1, and have thus found their way into a host of applications, notably detectors of people in such things as intruder alarms and remote light switches. Pyroelectric arrays have been developed in which a plane of pyroelectric material is interfaced to a silicon chip bearing a two-dimensional array of FET amplifiers and a set of switches which can be used to multiplex the pyroelectric signals onto a single output. These arrays have been used for uncooled thermal imagers with performances comparable to those that can be achieved with cooled semiconductor devices [27.32].

The requirements for the active materials in a pyroelectric device has been described by, for example, Whatmore [27.20], Whatmore and Watton [27.32]. There are two time constants that determine the frequency response of a pyroelectric device: the electrical time constant determined by $R_G(C_E + C_A)$ (see Fig. 27.17) and the thermal time constant determined by H/G where H is the heat capacity of the pyroelectric element and G the thermal conductance from the pyroelectric element

Table 27.7 Piezoelectric properties of PMN-PT and PZN-PT single-crystal materials [27.33] compared with those of a commercial soft-piezoelectric ceramic HD3203 [27.34]

Property	Composition	PZNT9307	PZNT9109	HD3203
$\epsilon_{33}^T/\epsilon_0$		3500	3000	3370
T_{RT} ($^\circ\text{C}$)		100	70	NA
T_C ($^\circ\text{C}$)		165	175	195
k_t (%)		58	56	0.536
k_{33} (%)		84	82	0.763
$N_{33,a}$		1230	1380	2000
d_{33} (pC/N)		1700	1900	564

to the environment. The capacitance of the element (C_E) is determined by the permittivity (ϵ) of the pyroelectric material while the heat capacity is determined by its specific heat per unit volume (c'). The pyroelectric current is proportional to the material's pyroelectric coefficient ($p = dP_s/dT$). A full treatment of the physics of device operation shows that detector performance (as determined by specific detectivity) is proportional to one of three basic figures-of-merit (FOMs), which combine the pyroelectric, dielectric and thermal properties of the pyroelectric material together. If the pyroelectric element capacitance is small in comparison with the amplifier capacitance (C_A), then the appropriate FOM is $F_I = p/c'$. If $C_E \gg C_A$ and the noise in the device is dominated by the amplifier noise sources, then the appropriate FOM is $F_V = p/c'\epsilon$. If the noise is dominated by alternating-current (AC) Johnson noise in the pyroelectric element then the appropriate FOM is $F_D = p/c'\sqrt{\epsilon \tan \delta}$, where $\tan \delta$ is the dielectric loss tangent of the pyroelectric material. Note that it is very important to measure the dielectric constant and loss at a frequency relevant to the device use. As most pyroelectric devices are used in the frequency range 0.1–100 Hz, and dielectric loss is usually much greater at < 100 Hz than at 1 kHz, a low-frequency measurement is essential. Table 27.7 lists the pyroelectric properties of several ferroelectric materials. Note that many of the literature papers on the subject only quote 1-kHz dielectric measurements. The differences between the FOM for the materials where high- and low-frequency data are available are clear. It can be seen that the TGS family gives the largest figures of merit. However, these materials are water soluble and have relatively low Curie temperatures and so they are only still used in the high-performance devices for instruments such as in Fourier-transform infra-red (FTIR) spectrometers. LiTaO₃ (LT) is a good pyroelectric material with relatively low permittivity.

It is inert and relatively easy to handle. It is used in many single-element detectors. Ceramic materials such as those based on modified PbZrO_3 (Mod PZ) or modified PbTiO_3 (Mod PT) are widely used in low-cost detectors. Note that, although their FOM are worse than LT, they are low cost and their performance is perfectly adequate for many applications. The **PVDF** family (represented here by a P(VDF/TrFE70/30 copolymer) have good F_V , but relatively low F_D values compared with the other materials listed. They tend to be used in large-area detectors because of their low permittivities, low cost and the fact that they are readily made in very thin films with low thermal mass, which is an advantage in some circumstances. They have been demonstrated in linear arrays. It is advantageous for very small-area detectors (say $< 100 \mu\text{m}$ square), such as those used in arrays, for the pyroelectric material to have a rel-

atively high permittivity (a few hundred) so that the detector can have a capacitance that matches the input capacitance of the **FET** amplifier (usually ca. 1 pF). The ceramic materials are well suited to this application for that reason. There has been considerable research into the use in thermal imaging arrays of ferroelectrics with T_C close to room temperature under an applied bias field, which will provide an induced pyroelectric effect well above the normal T_C . This has been called dielectric bolometer mode of operation and the best materials researched for this have been PST and $(\text{Ba}_x\text{Sr}_{1-x})\text{TiO}_3$ solid solutions with $x \approx 0.35$. These materials have relative permittivities of > 1000 under the operational conditions and very high pyroelectric coefficients which can give an effective F_D some three times greater than can be achieved using conventional pyroelectric ceramics [27.35].

28. Dielectric Materials for Microelectronics

Dielectrics are an important class of thin-film electronic materials for microelectronics. Applications include a wide swathe of device applications, including active devices such as transistors and their electrical isolation, as well as passive devices, such as capacitors. In a world dominated by Si-based device technologies, the properties of thin-film dielectric materials span several areas. Most recently, these include high-permittivity applications, such as transistor gate and capacitor dielectrics, as well as low-permittivity materials, such as inter-level metal dielectrics, operating at switching frequencies in the gigahertz regime for the most demanding applications.

This chapter provides a survey of the various dielectric material systems employed to address the very substantial challenge associated with the scaling Si-based integrated circuit technology. A synopsis of the challenge of device scaling is followed by an examination of the dielectric materials employed for transistors, device isolation, memory and interconnect technologies. This is presented in view of the industry roadmap which captures the consensus for device scaling (and the underlying economics) – the International Technology Roadmap for Semiconductors. Portions

of the survey presented here are selected from work previously published by the author [28.1–3].

This chapter considers the role of dielectric materials in microelectronic devices and circuits and provides a survey of the various materials employed in their fabrication. We will examine the impact of scaling on these materials, and the various materials utilized for their dielectric behavior. Extensive reviews are available on the device characteristics for the reader to consult [28.4–7]. We will primarily confine the discussion here to Si-based microelectronic circuits.

Dielectric materials are an integral element of all microelectronic circuits. In addition to their primary function of electrical isolation of circuit and device components, these materials also provide useful chemical and interfacial properties. The material (and result-

ing electrical) properties of dielectrics must also be considered in the context of the thin films used in semiconductor microelectronics, as compared to bulk properties. The dimensions of these dielectric thin films are determined by the device design of the associated integrated circuit technology, and these dimensions decrease due to a calculated design process called *scaling*.

28.0.1 The Scaling of Integrated Circuits

The ability to reduce the size of the components of integrated circuits (ICs), and therefore the circuits themselves, has resulted in substantial improvements in device and circuit speeds over the last 30 years. Equally

important, this calculated size reduction permits the fabrication of a higher density of circuits per unit area on semiconductor substrates. The economic implication of this scaling was captured by *G. Moore* more than 40 years ago [28.8].

Moore's Law

Moore observed that the minimum cost of manufacturing integrated circuits per component actually decreases with increasing number of IC components, and thus with greater circuit functionality and computing power. This is obviously an important economic driving force, as the ability to increase the number of circuits per unit area would lead to a lower minimum cost, and thus higher market demand and more potential profit. Moreover, Moore noted that the rate of increase in the number of components for a given circuit function roughly doubled each year in the early 1960s, and predicted that it would continue to do so through 1975. In 1975, *Moore* revised this estimate of doubling time to 24 months due to the anticipated complexity of circuits [28.9].

The semiconductor industry has generally confirmed (and aligned to meet) these extrapolations, often referred to as Moore's law, over the last 30 years. The extrapolation is often analyzed in the semiconductor industry, and the doubling period, which has varied between 17 and 32 months over the life of the industry, is now roughly 23 months [28.10]. Indeed the cost per transistor has decreased from ≈ 5 \$/transistor in 1965 to less than 10^{-6} \$/transistor today [28.11]. Current advanced Si IC production technology results in the fabrication of well over 500 000 000 transistors on a microprocessor chip.

Technology Roadmap

The contemporary industry analysis encompassing this observation is presented in the International Technology Roadmap for Semiconductors (ITRS) where the extrapolations of the future technological (and economic) requirements for the industry are annually updated [28.12]. The current scaling trends indicate that the compound annual reduction rate (CARR) in device dimensions is currently consistent with the following equation:

$$\text{CARR}(T) = \frac{1}{2} \left(\frac{1}{2^T} \right) - 1, \quad (28.1)$$

where T is the technology node cycle time measured in years. Thus in two years, the rate of reduction is -15.9% . This corresponds to a scaling factor of $\approx 0.7 \times$ from a given technology node to the next, or a factor of

$\approx 0.5 \times$ over the time of two technology nodes. Recent reviews and predictions for the limits of scaled integrated circuit technology continue to be available [28.13, 14].

Table 28.1 provides selected scaling targets from the ITRS through 2010 [28.12]. As may be seen, the industry roadmap now segregates scaling targets among three categories: microprocessor (MPU)/application-specific IC (ASIC) applications, low-operational-power applications, and low-stand-by-power applications. Higher-performance technologies, such as MPU/ASIC applications, require aggressive scaling, while low-stand-by-power applications require less-aggressive scaling. A key criteria to enable these technologies is the associated power management in the *on* and *off* state, hence leakage current remains an important distinction amongst the various roadmap applications.

Performance and Scaling

The concomitant reduction in device dimensions, such as transistor channel length, associated with increasing the number of components per unit area has resulted in a significant increase in processing performance – the speed at which computations can be done. For example, as scaling reduces the distance that carriers must travel in a transistor channel, the response time of the transistor as a digital switch also decreases (as long as sufficient mobility is maintained). Scaling has resulted in the speeds of microprocessors increasing from 25–50 MHz clock frequencies in the early 1990s ($\approx 10^6$ transistors) to 2.2 GHz in 2003 ($\approx 10^8$ transistors) [28.15]. Current predictions suggest that 20-GHz frequencies are possible for complementary metal oxide semiconductor (CMOS)-based microprocessors incorporating 10^9 transistors [28.11].

The various dielectric materials associated with the components impacts the overall performance of the corresponding IC technology. In the case of transistors, the gate dielectric is integral to the performance of transistor electrical characteristics such as the drive current I_d . The interconnection performance of circuit elements is influenced by the dielectric material that isolates the various metal interconnection lines through the line-to-line capacitance. Memory elements incorporate very-low-leakage dielectric materials for charge-storage purposes. The behavior of these materials with component size reduction is thus an important design consideration in IC technology.

Figure 28.1 shows the dependence of the delay time as a function of technology node (scaling) associated with conventional CMOS transistor gates interconnected with metal lines that are isolated with different di-

electronics [28.16]. The total delay time associated with the circuit response for a given technology node is a combination of the temporal response of the transistor gate (influenced by the gate capacitance) as well as the propa-

gation through the interconnecting wire lines associated with the circuit [influenced by the wire resistance and the line-to-line capacitance, i.e. a resistive-capacitive (RC) delay] [28.16, 17]. Changing both the interconnect wire material (from Al to Cu) to decrease the line resistivity as well as decreasing the dielectric constant in the material isolating these lines (from SiO_2 to a lower dielectric constant material) to decrease line-to-line parasitic capacitance minimizes the overall RC delay time response. Of course, the challenge in adopting this solution was the successful integration of these material changes into a high-volume fabrication line, which took the investment of considerable time and effort.

In order to compare the performance of different CMOS technologies, one can consider a performance metric that captures the dynamic response (i.e. charging and discharging) of the transistors associated with a specific circuit element to the supply voltage provided to the element at a representative (clock) frequency [28.1, 18, 19]. A common element employed to examine such switching-time effects in a new transistor design technology node is a CMOS inverter. This circuit element is shown in Fig. 28.2 where the input signal is attached to the gates and the output signal is connected to both the n-type MOS (NMOS) and p-type MOS (PMOS) transistors associated with the CMOS stage. The switching time is limited by both the fall time required to discharge

Fig. 28.1 Time delay contributions for integrated circuits. The resultant delay is dependent upon the circuit architecture as well as the material constituents. After [28.16] (© 2004 IEEE, with permission)

Fig. 28.2 Example circuits employed to evaluate the performance of a transistor technology. For example, elements are combined to simulate processor performance adequately. After [28.1] (AIP, with permission© 2001)

the load capacitance by the n-type field-effect transistor (n-FET) drive current and the rise time required to charge the load capacitance by the p-FET drive current. That is, the switching response times τ are given by:

$$\tau = \frac{C_{\text{LOAD}} V_{\text{dd}}}{I_d}, \quad \text{where}$$

$$C_{\text{LOAD}} = FC_{\text{GATE}} + C_j + C_i, \quad (28.2)$$

and C_j and C_i are the parasitic junction and local inter-connection capacitances, respectively. Of course, as one considers the combination of transistors to produce various circuit logic elements to enable computations (viz. a *processor*), it is also clear that the manner in which the transistors are interconnected also plays an important role on the overall performance of the circuit. The *fan out* for interconnected devices is given by the factor F . Ignoring delay in the gate electrode response, as $\tau_{\text{GATE}} \ll \tau_{n,p}$, the average switching time is therefore:

$$\bar{\tau} = \frac{\tau_p + \tau_n}{2} = C_{\text{LOAD}} V_{\text{dd}} \left(\frac{1}{I_d^n + I_d^p} \right). \quad (28.3)$$

The load capacitance in the case of a single CMOS inverter is simply the gate capacitance if one ignores parasitic contributions such as junction and interconnect capacitance. Hence, an increase in I_d is desirable to reduce switching speeds. For more realistic estimates of microprocessor performance, the load capacitance is connected (*fanned out*) to other inverter elements in a predetermined fashion. When coupled with other NMOS/PMOS transistor pairs in the configuration shown in Fig. 28.2, one can create a logic NAND gate, which can be used to investigate the dynamic response of the transistors and thus examine their performance under such configurations. For example, a fan out $F = 3$ can be employed in microprocessor performance estimates, as shown in Fig. 28.2.

One can then characterize the performance of a circuit technology (based on a particular transistor structure) through this switching time. To do this, various *figures of merit* (FOM) have been proposed that incorporate parasitic capacitance as well as the influence of gate sheet resistance on the switching time [28.18–20]. For example, a common FOM employed is related to (28.3) simply by

$$\text{FOM} \cong \frac{1}{\bar{\tau}} = \frac{2}{\tau_p + \tau_n}. \quad (28.4)$$

In the case where parasitic capacitance and resistance effects are ignored, it is easily seen then that an increase in the device drive current I_d results in a decrease in the switching time and thus an increase in the FOM value (performance). However, the incorporation of parasitic effects results in the limitation of FOM improvement, despite an increase in the gate dielectric capacitance. All of these issues depend critically upon the materials constituents of the integrated circuit, and dielectrics are an important component [28.1].

Impact of Scaling on Dielectrics

The scaling associated with the device dimensions that constitute an integrated circuit impacts on virtually all film dimensions such as thickness, including the dielectrics employed in the circuit. Various scaling methodologies have been applied since the pioneering work by Dennard and coworkers [28.21, 22]. These various methods have been recently summarized [28.5, 23]. For example, following the work by Dennard et al., the scaling of the transistor from one node N to the next $N + 1$ under a constant-electric-field condition would result in a relationship between the *new* transistor gate (or channel) length $L_{N+1} = L_N/\alpha$, where $\alpha > 1$ is the constant scaling factor (Fig. 28.3). Other dimensions, such as the gate dielectric thickness and the gate width,

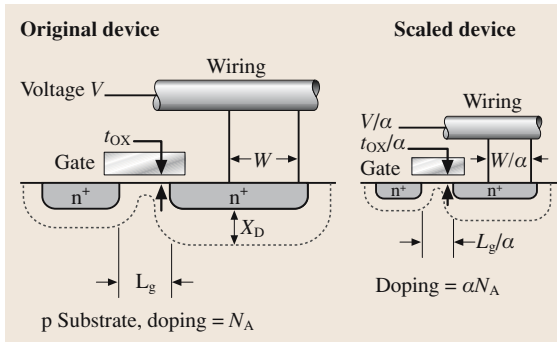

Fig. 28.3 Scaling methodology for integrated circuit technology. After [28.23] (© 2004 IEEE, with permission)

scale similarly. The voltage would also scale according to $V_{N+1} = V_N/\alpha$ in this scenario as well. Table 28.1 provides the drive voltage scaling (V_{dd}) anticipated by the ITRS roadmap, depending upon the application.

This scaling approach has several shortcomings, including the reduction of power-supply voltages with each node, raising problems with circuit power-supply compatibility. So, for earlier technology nodes ($L \geq 0.35 \mu\text{m}$), the power supply was kept constant while the device dimensions were scaled as described above. Eventually, the resultant higher electric fields associated with this scaling approach led to reliability

concerns for the gate dielectric, mobility degradation and hot-carrier effects. For further scaling, the power supply was scaled at a different factor (such as $\alpha^{1/2}$) to compensate for such effects. For modern devices with *deep-submicron* gate length, other techniques are used to scale from node to node. Nevertheless, for CMOS technology over the last ≈ 25 years, it has been noted that the gate dielectric thickness can be related to the channel length as shown in Fig. 28.4 for a wide variety of device technologies [28.24].

The critical point in the context of dielectric films is that the dimensions of the devices, and therefore the dimensions (thicknesses) of the dielectric layers, are significantly reduced as scaling proceeds (Table 28.1). At some point, the materials properties associated with the dielectric in a component will be predicted to no longer provide the desirable electrical behavior attained in previous nodes, thus stimulating research on new dielectric materials. In the case of gate dielectrics, scaling results in thinner layers to a point where quantum-mechanical tunneling becomes an issue. For memory capacitor dielectrics, a specific capacitance density is required, regardless of capacitor dimensions, for a reliable memory element. Indeed, scaling impacts on the selection and integration of numerous constituents of electronic devices including gate electrode materials, source/drain junction regions, contacts, interconnect dielectrics.

Fig. 28.4 Scaling trends of the transistor gate length and the gate insulator thickness for various generations of integrated technologies. The *solid line* is a linear fit to the data. The *dashed line* represents the approximate scaling trend between the gate dielectric thickness and gate length observed over several technology generations: $L_G = 45 \times t_{ox}$. 28.0.2 Role of Dielectrics for ICs

Dielectrics are pervasive throughout the structure of an integrated circuit. Applications include gate dielectrics, tunneling oxides in memory devices, capacitor dielectrics, interconnect dielectrics and isolation dielectrics, as well as sacrificial or masking applications during the circuit fabrication process.

The basic properties utilized in dielectric materials include their structure and the resultant polarizability behavior. As noted in Fig. 28.5, there are several mechanisms to consider in the polarization of materials in the presence of an electric field. For nonmetallic (insulating) solids in CMOS applications, there are two main contributions of interest to the dielectric constant which give rise to the polarizability: electronic and ionic dipoles. Figure 28.5 illustrates the frequency ranges where each contribution to the real part of the complex relative dielectric permittivity ϵ_r dominates, as well as the imaginary part of the complex permittivity (dielectric losses), ϵ_r'' [28.25]. The region of interest to CMOS applications includes the shaded area where switching frequencies are in the GHz range at the present time.

Fig. 28.5 Schematic of the dependence of dielectric permittivity on frequency. After [28.25], with permission

In general, atoms with a large ionic radius (i.e. high atomic number, Z) exhibit more electron dipole response to an external electric field, because there are more electrons to respond to the field (electron screening effects also play a role in this response). This electronic con-

tribution tends to increase the permittivity of materials with higher- Z atoms.

The ionic contribution to the permittivity can be much larger than the electronic portion in cases such as perovskite crystals of $(\text{Ba},\text{Sr})\text{TiO}_3$ (BST) and $(\text{Pb},\text{Zr})\text{TiO}_3$ (PZT), which exhibit ferroelectric behavior below the Curie point. In these cases, Ti ions in unit cells throughout the crystal are uniformly displaced in response to an applied electric field (for the case of ferroelectric materials, the Ti ions reside in one of two stable, non-isosymmetric positions about the center of the Ti–O octahedra). This displacement of Ti ions causes an enormous polarization in the material, and thus can give rise to very large dielectric constants in bulk films of 2000–3000, and has therefore been considered for dynamic random-access memory (DRAM) capacitor applications [28.26, 27]. Since ions respond more slowly than electrons to an applied field, the ionic contribution begins to decrease at very high frequencies, in the infrared range of $\approx 10^{12}$ Hz, as shown in Fig. 28.5.

28.1 Gate Dielectrics

28.1.1 Transistor Structure

A cross-sectional schematic of the structure of a metal–oxide–semiconductor (MOS) field-effect transistor (FET) and a modern CMOS transistor, consisting of the n-FET and p-FET pair, is shown in Fig. 28.6. The source- and drain-region dopant profiles reflect modern planar CMOS technologies where an extended, doped region is produced under the gate region in the channel. Additionally, so-called *halo* or *pocket* dopant implantation regions are also shown. These dopant profile approaches have been incorporated in recent years in an effort to permit transistor channel scaling and yet maintain performance [28.28].

As can be seen, there exist several regions of the device which require dielectric materials to enable useful transistor operation. Both n-MOS and p-MOS transistors are isolated with a dielectric, typically deposited SiO_2 in most modern device technologies, which is deposited in trench structures. This isolation technique is called *shallow trench isolation* (STI) as the associated trench depth is $\leq 0.5\ \mu\text{m}$. Earlier generations of CMOS (and often devices under research) also utilized the so-called local oxidation of silicon (LOCOS) isolation approach [28.29, 30]. So-called spacer dielectrics (typically SiO_2 , SiO_xN_y , or SiN_x) are also used around

the transistor *gate stack* for isolation and implantation-profile control. The gate stack is defined here as the films and interfaces comprising the gate electrode, the underlying gate dielectric, and the channel region. The gate dielectric, typically SiO_2 or SiO_xN_y for transistors currently in production, electrically isolates the gate electrode from the underlying Si channel region while allowing the modulation of the carrier flow in the channel. As we shall see, the interface between the gate dielectric and the channel regions is particularly important in regard to device performance.

28.1.2 Transistor Dielectric Requirements in View of Scaling

In addition to the thickness reduction associated with scaling, the gate dielectric must adhere to several requirements that are dependent upon the specific product application, including adequate drive current, suitable capacitance, minimal leakage current, and reliable performance. Table 28.1 provides some selected values describing the ITRS 2003 roadmap.

Drive Current

The improved performance associated with the scaling of logic device dimensions can be seen by consider-

ing a simple model for the drive current associated with a FET [28.1, 3, 18, 20]. In the gradual channel approximation, the drive current can be written as:

$$I_d = \frac{W}{L} \mu C_{\text{inv}} \left(V_G - V_T - \frac{V_D}{2} \right) V_D, \quad (28.5)$$

where W is the width of the transistor channel, L is the channel length, μ is the channel carrier mobility (assumed to be constant in this analysis), C_{inv} is the capacitance density associated with the gate dielectric when the underlying channel is in the inverted state, V_G and V_D are the voltages applied to the transistor gate and drain, respectively, and the threshold voltage is given by V_T . It can be seen that in this approximation the drain current is proportional to the average charge across the channel (with a potential $V_D/2$) and the average electric field (V_D/L) along the channel direction. Initially, I_D increases linearly with V_D and then eventually saturates to a maximum when $V_{D,\text{sat}} = V_G - V_T$ to yield:

$$I_{D,\text{sat}} = \frac{W}{L} \mu C_{\text{inv}} \frac{(V_G - V_T)^2}{2}. \quad (28.6)$$

A goal here is to increase the saturation drive current as much as possible for a given transistor technology design. The term $(V_G - V_T)$ is limited in range due to reliability concerns as too large a V_G would create an undesirable, high electric field across the gate dielectric. Moreover, practical operation of the device at room temperature (or above) requires that V_T cannot easily be reduced below about $8 \times k_B T \cong 200$ meV ($k_B T \approx 25$ meV at room temperature). Elevated operating temperatures could therefore cause statistical fluctuations in thermal energy, which would adversely affect the desired V_T value. Thus, even in this simplified approximation, one is left to pursue a reduction in the channel length, increasing the width, increasing the gate dielectric capacitance, or a carefully engineered combination of all of these in order to increase $I_{D,\text{sat}}$. Note that none of these dimensions are, in reality, independent and so substantial resources are utilized to simulate device performance in order to maximize the performance prior to the fabrication of a representative transistor [28.5, 30, 32].

Gate Capacitance

In the case of increasing the inversion capacitance to improve I_D , consider the gate stack structure idealized as a parallel-plate capacitor (ignoring quantum-mechanical and depletion effects from a Si substrate and

Fig. 28.6a,b Important regions of (a) a MIS field-effect transistor, and (b) a planar CMOS transistor structure. After [28.31] (© 2004 IEEE, with permission)

gate [28.33]),

$$C = \frac{\kappa \epsilon_0 A}{t}, \quad (28.7)$$

where κ is the dielectric constant of the material, ϵ_0 is the permittivity of free space ($= 8.85 \times 10^{-3}$ fF/ μm), A is the area of the capacitor, and t is the thickness of the dielectric between the capacitor electrode plates. (Note that the relative permittivity of a material is often given by ϵ or ϵ_r , such as with the expression $C = \epsilon \epsilon_0 A/t$. Note that the relation between κ and ϵ varies depending on the choice of units (e.g. when $\epsilon_0 = 1$), but since it is always the case that $\kappa \approx \epsilon$, we shall assume here that $\kappa = \epsilon$.) It is clear that transistor designs utilizing planar CMOS scaling approaches discourage increasing the area of the capacitor, and so one is left to considering the reduction of the dielectric thickness in order to increase the capacitance.

In order to compare alternative dielectric materials which exhibit a dielectric constant higher than the standard for the industry, SiO_2 , this expression for C can also be rewritten in terms of t_{eq} (i.e. equivalent oxide thickness) and $\epsilon \kappa_{\text{ox}}$ of the capacitor ($\kappa_{\text{ox}} = 3.9$

for the low-frequency dielectric constant of SiO_2). The term t_{eq} then represents the theoretical thickness of SiO_2 that would be required to achieve the same capacitance density as the dielectric (ignoring important issues such as leakage current and reliability). For example, if the capacitor dielectric is SiO_2 , $t_{\text{eq}} = 3.9 \varepsilon_0(A/C)$, and so a capacitance density of $C/A = 34.5 \text{ fF}/\mu\text{m}^2$ corresponds to $t_{\text{eq}} = 10 \text{ \AA}$.

Thus, the physical thickness of an alternative high- κ dielectric employed to achieve the equivalent capacitance density of $t_{\text{eq}} = 10 \text{ \AA}$ can be obtained from the expression

$$\frac{t_{\text{eq}}}{\kappa_{\text{ox}}} = \frac{t_{\text{high-}\kappa}}{\kappa_{\text{high-}\kappa}} \quad \text{or simply,}$$

$$t_{\text{high-}\kappa} = \frac{\kappa_{\text{high-}\kappa}}{\kappa_{\text{ox}}} t_{\text{eq}} = \frac{\kappa_{\text{high-}\kappa}}{3.9} t_{\text{eq}}. \quad (28.8)$$

From this expression, a dielectric with a relative permittivity of 16 therefore results in a physical thickness of $\approx 40 \text{ \AA}$, to obtain $t_{\text{eq}} = 10 \text{ \AA}$. The increase in the physical thickness of the dielectric impacts on properties such as the tunneling (leakage) current through the dielectric, and is discussed further below.

The industry scaling process clearly presents a major challenge for the core transistor gate dielectric as predictions call for a much thinner effective thickness for future alternative gate dielectrics: $t_{\text{eq}} \leq 1 \text{ nm}$ [28.12]. The interfacial regions between the gate electrode, dielectric and channel [in totality termed the metal–insulator–semiconductor (MIS) *gate stack* as shown schematically in Fig. 28.7] require careful attention, as they are particularly important in regard to transistor performance. These regions, less than approximately 0.5 nm thick, serve as a transition between the atoms associated with the materials in the gate electrode, gate dielectric and Si

channel, and can alter the overall capacitance of the gate stack, particularly if they have a thickness that is substantial relative to the gate dielectric. Additionally, these interfacial regions can be exploited to obtain desirable properties. The upper interface, for example, can be engineered in order to block boron out-diffusion from the poly-Si gate. The lower interface, which is in direct contact with the CMOS channel region, must be engineered to provide low interface trap densities (e.g. dangling bonds) and minimize carrier scattering (maximize channel carrier mobility) in order to obtain reliable, high-performance device. Mobility degradation, relative to that obtained using SiO_2 (or SiON) gate dielectrics, associated with the incorporation of high- κ gate dielectrics is an important issue currently under investigation and discussed further below.

Reactions at either of these interfaces during the device fabrication process can result in the formation of a significant interfacial layer that will likely reduce the desired gate stack capacitance. Additionally, any suitable interfacial layer near the channel must result in a low density of electrically active defects ($\lesssim 10^{11}/\text{cm}^2\text{eV}$ is often obtained for SiO_2) and avoid degradation of carrier mobility in the region near the surface channel.

The reduced capacitance can be seen by noting that the dielectric film that has undergone interfacial reactions results in a structure that essentially consists of several dielectric layers in series. If we suppose that the dielectric consists of two layers, then from electrostatics the total capacitance of two dielectrics in series is given by $1/C_{\text{tot}} = 1/C_1 + 1/C_2$, where C_1 and C_2 are the capacitances of the two layers. Thus, the lowest-capacitance layer will dominate the overall capacitance and also set a limit on the minimum achievable t_{eq} value. If we consider a dielectric stack structure such that the bottom layer (layer 1) of the stack is SiO_2 , and the top layer (layer 2) is the high- κ alternative gate dielectric, (28.8) is expanded (assuming equal areas) to:

$$t_{\text{eq}} = t_{\text{SiO}_2} + \frac{\kappa_{\text{SiO}_2}}{\kappa_{\text{high-}\kappa}} t_{\text{high-}\kappa}. \quad (28.9)$$

From (28.9), it is clear that the layer with the lower dielectric constant (SiO_2 in this case) limits the ultimate capacitance of the MIS gate stack.

Of course, the actual capacitance of a CMOS gate stack for ultra-large-scale integration (ULSI) devices does not scale simply with $1/t$ due to parasitics, quantum-mechanical confinement of carriers, and depletion effects. Indeed, consideration of these important effects can result in much confusion on the defini-

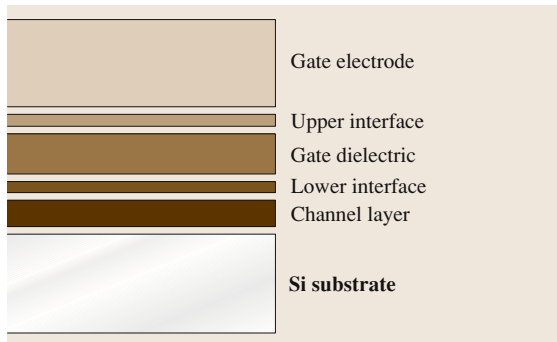

Fig. 28.7 Schematic of the important regions of the transistor gate stack. After [28.1] (AIP, with permission © 2001)

tion of dielectric thickness as extracted from electrical measurements.

Parasitic resistances and capacitances associated with various portions of the transistor structure can result in an overall degradation of performance as defined by a delay time figure of merit [28.1, 19]. There exist several materials issues associated with the control of such parasitics including source/drain dopant-profile control, gate/contact sheet resistance minimization, etc. which are beyond the scope of this chapter.

Quantum-mechanical confinement effects on carriers in the channel region occur as a result of the large electrical fields in the vicinity of the Si substrate surface. These fields quantize the available energy levels resulting in the displacement of the charge centroid from the interface into the Si and at energies above the Si conduction-band edge. The extent of the penetration of the charge centroid is dependent upon the biasing conditions employed for the metal–insulator–semiconductor (MIS) structure and, for accurate estimates of transistor drain-current performance, the inversion capacitance measurement provides accurate determination of the equivalent oxide thickness [28.33, 36, 37].

Current MIS gate-stack structures employ heavily doped polycrystalline Si (poly-Si) as the *metal* gate electrode for CMOS transistors. Poly-Si gates were introduced as a replacement for Al metal gates in the 1970s for CMOS integrated circuits and have the very desirable property of a tunable work function for both n-MOS and p-MOS transistors through the implantation of the appropriate dopant into the poly-Si gate electrode.

However, in deep-submicron scaled devices, the *poly-Si depletion effect* impacts the overall gate-stack capacitance significantly, as the scaling results in an increased sensitivity to the effective *electrical* thickness resulting from all of the gate-stack component films, including the gate electrode. The depletion effect (which occurs in any doped semiconductor) is a result of the decrease in the density of majority carriers near the poly-Si/dielectric interface upon biasing, resulting in an increased depletion width in the poly-Si [28.28, 38]. This results in a voltage drop across the depletion region, rendering a smaller voltage drop across the remaining portions of the gate stack (i.e. the dielectric and the substrate). As a result, the (low-frequency) capacitance under strong inversion biasing conditions is significantly lower than that obtained under accumulation (Fig. 28.8). Moreover, the inversion-layer charge in the substrate is reduced from that possible in the ideal case where no depletion layer exists in the gate (i.e. an ideal metal conductor for the gate electrode). This reduction in the

Fig. 28.8 Capacitance–voltage curves demonstrating the effects of poly-Si depletion and quantum-mechanical behavior for scaled transistors. N_{sub} and N_{poly} denote the dopant density for the substrate and poly-Si gate, respectively. After [28.34]

Fig. 28.9 Metrology results for various measurement techniques of the thickness of thin SiO₂ films. X-ray photoelectron spectroscopy (XPS) measured thicknesses are compared to thicknesses derived from high-resolution transmission electron microscopy (HRTEM), C–V and ellipsometry. After [28.35] (AIP, with permission © 1997)

inversion-layer charge in turn reduces the ideal transistor drive current. As the dielectric thickness is reduced in the scaling process, this effect becomes a serious limitation for transistor drive current.

To solve this problem, a return to metal gate electrode materials is now under development to eliminate any depletion region in the gate, and thus the interaction of any dielectric with various metal gate candidates is of interest. Compatibility of dielectric materials with metal gate materials is briefly discussed later in this chapter.

When a capacitance–voltage curve is properly corrected for these quantum-mechanical and dopant depletion effects, as seen in Fig. 28.8, one can accurately extract the equivalent oxide thickness (EOT), t_{eq} [28.34]. This thickness definition is in contrast to that derived directly from the raw data in a capacitance–voltage (C–V) measurement, which is termed the *capacitance equivalent thickness* (CET > EOT), or the *physical thickness*, which can be determined by non-electrical characterization methods such as ellipsometry or high-resolution transmission electron microscopy, as seen in Fig. 28.9 [28.34, 35]. Please note that thicknesses derived from quantum-mechanical-corrected accumulation capacitance data are also often abbreviated as t_{qm} .

Leakage Current

Of course, physically thinning the dielectric layer to the nanometer regime raises the prospect of quantum-mechanical tunneling through the dielectric – often referred to as *leakage*. To minimize gate leakage (tunneling) currents, quantum mechanics indicates that the gate dielectric must be sufficiently thick and have a sufficient energy barrier (band offset) to minimize the resultant tunneling current. Consider the band diagram shown in Fig. 28.10, where the electron affinity (χ) and gate

electrode work function (Φ_M) are defined (q is the charge). For electrons traveling from the Si substrate to the gate, this barrier is the conduction-band offset, $\Delta E_C \cong q[\chi - (\Phi_M - \Phi_B)]$; for electrons traveling from the gate to the Si substrate, this barrier is Φ_B . The effect of the height of the energy barrier and the film thickness on tunneling current can be seen by considering the expression for the direct tunneling current where electron transport occurs through a trapezoidal energy barrier [28.18]:

$$J_{dt} = \frac{A}{t_{diel}^2} \exp(-Bt_{diel}) \times \left\{ \left(\Phi_B - \frac{V_{diel}}{2} \right) \exp \left[\sqrt{\left(\Phi_B - \frac{V_{diel}}{2} \right)} \right] - \left(\Phi_B + \frac{V_{diel}}{2} \right) \exp \sqrt{\left(\Phi_B + \frac{V_{diel}}{2} \right)} \right\}. \quad (28.10)$$

Here A is a constant, $B = 4\pi/h(2m^*q)^{1/2}$, Φ_B is the potential-energy barrier associated with the tunneling process, t_{diel} is the physical thickness of the dielectric, V_{diel} is the voltage drop across the dielectric, and m^* is the electron effective mass in the dielectric. From (28.10), one observes that the tunneling (leakage) current increases exponentially with decreasing barrier height and thickness for electron direct-tunneling transport. In the context of charge transport through the dielectric, electrically active defects (electron or hole traps) can result in charging of the dielectric, which in turn deleteriously affects the electric field in the channel region and therefore mobility. Conduction mechanisms through such fixed charge traps can also be evaluated through electrical characterization techniques [28.18]. In the case of dielectrics layers, tunneling transport has also been previously examined [28.39].

The introduction of a dielectric material that exhibits a suitable energy barrier and thickness, while performing electrically as a thin SiO₂ layer, is now a key research and development goal for the industry to continue the scaling trend. It is also clear that the gate dielectric must exhibit adequate thickness uniformity and integrity over the surface of the wafer. The reduction of this leakage current impacts important circuit properties such as stand-by power consumption, as shown in Fig. 28.11. With the minimization of leakage current as a key driving force, alternate gate dielectric materials appear to be required for low-power CMOS device technologies in the near future and are therefore the subject of intense research.

Reliability

Any gate dielectric material must possess the ability to enable a specified, stable operational lifetime for the transistor. Key areas of concern in this regard includes defect generation/mitigation resulting in dielectric breakdown phenomenon, charge formation within the dielectric and at the associated interfaces, and resistance to energetic (“hot”) carrier interactions. This is often evaluated in the context of accelerated lifetime testing through electrical stressing in combination with thermal stressing of devices. Reviews on these topics can be found in this handbook as well as other sources [28.6, 28.40, 41].

28.1.3 Silicon Dioxide

As articulated by *Hummel*, silicon has an amazing number of desirable materials (and therefore electronic) properties that no other electronic material can rival [28.42]. Silicon constitutes 28% of the Earth’s crust, it is nontoxic, exhibits a useful band gap ($E_G = 1.12 \text{ eV}$) for applications at room temperature, and can be grown in crystalline form (from abundant sand, i.e. SiO_2). However, it can be argued that the ability of Si to form the stable, high-quality insulator, SiO_2 , may be the primary reason that Si-based transistor technology

Table 28.2 Properties of SiO_2

Geometrical parameters	
Si–Si bond length	3.12 Å
Si–O bond length	1.62 Å
O–O bond length	2.27 Å
Mean bond angle	144° (tetrahedral bonding)
Bond angle range	Si–O–Si: 110° to 180°
Density (g/cm^3)	
Thermally grown (fused silica)	2.20
Quartz	2.65
Index of refraction (optical frequencies)	
Thermally grown (fused silica)	1.460
Quartz	1.544
Quasi-static dielectric constant ($\leq 1 \text{ kHz}$)	
Thermally grown (fused silica)	3.84
Quartz	3.85
Band gap	
Thermally grown (fused silica)	8.9 eV
Quartz	$\approx 9.0 \text{ eV}$
Electrical breakdown strength	
Thermally grown (fused silica)	10 MV/cm
Quartz	$\approx 10 \text{ MV/cm}$

has dominated the industry since the 1960s [28.8, 43]. This compound has a number of material properties that result in outstanding electrical performance. Some of these properties are summarized in Table 28.2. Over the last 25 years, abundant compendia of the properties of SiO_2 with particular emphasis on materials and electrical properties have been published, as well as conferences which have focused almost exclusively on SiO_2 [28.44–53].

It is noteworthy that the early development of transistor technology utilized the semiconductor Ge, which has a rather unstable oxide, GeO_2 , that is water soluble. The utilization of crystalline Si and its stable oxide presented a superior solution for the practical manufacturing of the planar transistor and the associated integrated circuit of the era [28.43]. It was the utilization of the properties of SiO_2 that resulted in the dominance of Si-based device technology over Ge-based technology in the 1960’s.

Bonding Arrangements for Thin SiO_2

As can be seen in Fig. 28.12, the phase diagram for SiO_2 has a number of crystalline phases and associated polymorphisms [28.52, 54]. In the context of accessible phase space appropriate for typical CMOS processes (pressure $\approx 1 \text{ bar}$ and $T \leq 1100^\circ\text{C}$), the quartz and tridymite

Fig. 28.12a,b Phase diagram for SiO_2 . *Inset:* bonding configurations for the O–Si–O system. **(a)** Tetrahedral unit for the Si–O bonding arrangement. **(b)** Bond angle θ defined for O–Si–O bonds. After [28.54] (IOP Publishing © 1994, with permission)

phases are stable [28.55]. High-pressure phases are also well studied [28.56].

The bulk SiO_2 tetrahedral bonding coordination (inset, Fig. 28.12) results in an average Si–O–Si bond angle of $\theta \approx 145^\circ$ [28.57] comparable to that observed for vitreous silica [28.54, 58]. As noted originally in the classic work by Zachariasen, the bonding interconnections among the various SiO_4 tetrahedra can result in an amorphous SiO_2 film consisting of locally ordered ring structures commonly observed in silica glasses [28.50, 52, 59]. The numerous available variations of the ring structure provide substantial flexibility and minimize bond strain and the density of defects at interfaces [28.60].

For the purposes of microelectronic applications, we first consider so-called *thermally grown* SiO_2 . As the name implies, a SiO_2 layer is formed on Si

from a thermally activated oxidation process (often referred to as a *thermal oxide*) rather than simply a (low-temperature) deposition process. Thermal oxide films are stable enough to endure high-temperature ($\approx 1000^\circ\text{C}$) post-implantation/dopant activation anneals. These films have useful electrical properties including a stable (thermal and electrical) interface with minimal electrically-active-defect densities ($\approx 10^{10}/\text{cm}^2$) as well as high breakdown strength ($\approx 10\text{ MV/cm}$) over a large area ($\approx 1\text{ cm}^2$) [28.18]. The breakdown strength is important for high reliability of devices fabricated with a dielectric, as the scaling of devices typically results in somewhat higher electric fields across the oxide.

Recent experimental results on thin thermal SiO_2 [28.34, 40, 61] combined with modern computational modeling [28.57, 62] of the defects associated with the $\text{SiO}_2/\text{Si}(001)$ interface, which is the dominant microelectronic materials system, and *bulk* SiO_2 [28.63] has provided a reasonably consistent picture of the known defects and interface structure.

High-resolution X-ray photoelectron spectroscopy (XPS) evidence, coupled with other experimental and theoretical modeling results, appears to support the presence of SiO_x ($x = 4$) species (often called *sub-oxides*) detected as a chemical shift in the associated Si oxidation states (Fig. 28.13) [28.64–67].

More recent high-resolution angle-resolved XPS analysis of ultrathin (6-Å) SiO_2 has resulted in a further understanding of the average oxidation state observed with depth along the interfacial transition region [28.68, 69]. From these experimental results, models of the interface have been constructed from first-principles methods that reproduce the experimental results, as shown in Fig. 28.14 [28.57, 62]. As seen in Fig. 28.14, the transition region between the Si substrate and the SiO_2 consists of interfacial suboxide species of varying abundance (and therefore density). These results appear to be in general agreement with recent high-resolution transmission electron microscopy as well [28.70].

Oxidation Kinetics of Si

The oxidation kinetics of Si have also been exhaustively studied and reviewed [28.28, 40, 71]. Two regimes for oxidation are generally characterized as *passive* and *active* in nature. The passive oxidation regime refers to the low-temperature/high-pressure region of the pressure–temperature (p – T) phase space shown in Fig. 28.15 [28.40, 72–77]. In this portion of the p – T phase space, the reaction between Si and O_2 proceeds

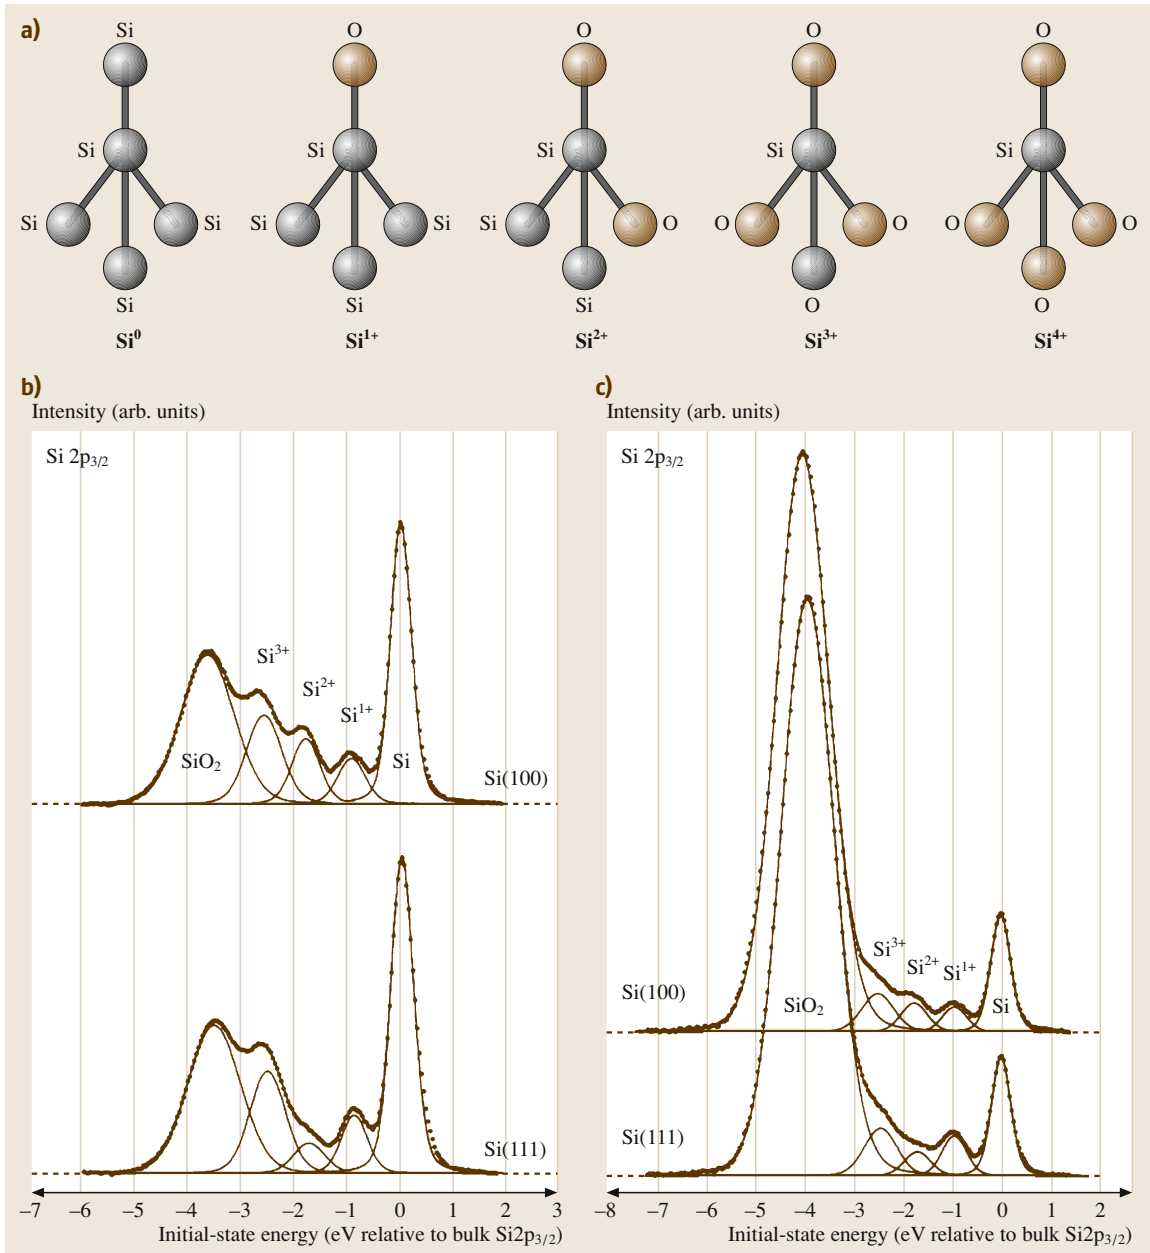

Fig. 28.13 (a) Oxidation states and local chemical bonding variations associated with the Si–SiO₂ interface. After [28.54]. as a surface reaction resulting in a thin (≤ 2 -nm) SiO_x layer, where $0.5 \leq x \leq 2$. Decreasing pressure and increasing temperature during the reaction re-

sults in both Si etching and oxidation – the so-called *active* regime – and the formation of thicker SiO₂ films.

Fig. 28.15 Pressure–temperature phase diagram for thin SiO₂/Si. After [28.77] (© 1997 AIP, with permission)

The clever utilization of isotopic labeling techniques coupled with depth profiling from ion scattering [28.78]

and nuclear reaction analysis [28.71] has generally confirmed that molecular oxygen (O₂) is the mobile species that interstitially diffuses through a growing oxide and only reacts at the Si interface to form the SiO₂ on the Si surface, as first empirically proposed by *Deal and Grove* in 1965 for SiO₂ thicker than about 4 nm [28.79,80]. The details of the oxidation process for thin films deviates from the Deal–Grove model, and is discussed thoroughly in the review by *Green et al.*, for example [28.40].

Defects for Thin SiO₂

In addition to the electrical breakdown strength associated with SiO₂, the physicochemical properties of the interface between the substrate Si and SiO₂ plays a major role in establishing the observed electrical properties [28.61,67]. Like all interfaces of solids, the interface between bulk Si and bulk SiO₂ naturally results in the presence of point defects (Fig. 28.16). Examples include strained bonds, atoms that are not fully bonded to neighboring atoms (so-called “dangling”), bonds and hydrogenic species bonded among the Si–O bonding network. These defects can result in energy levels in the band structure associated with an MIS device, and serve as *traps* for carriers (electrons and holes).

The dominant orientation for contemporary Si-based integrated circuit technology substrates is Si(100). This is, of course, no accident and the choice of the substrate

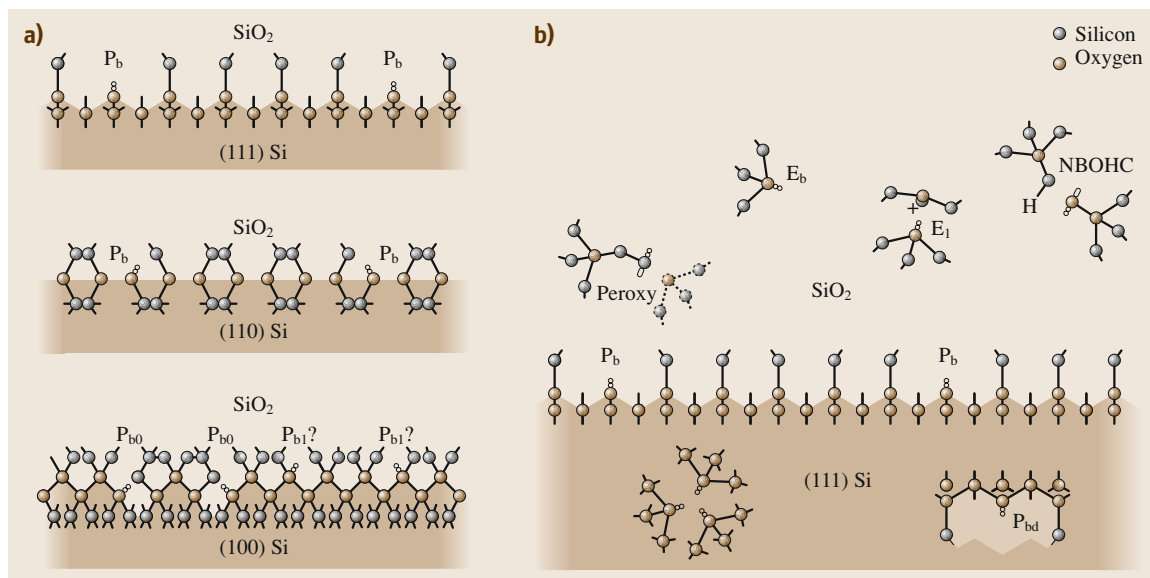

Fig. 28.16a,b Schematic representations of **(a)** the various point defects for the SiO_2/Si interface and **(b)** bulk SiO_2 . After [28.54] (IOP, with permission © 1994)

orientation has much to do with the resultant SiO_2/Si interface. Early in the development of Si-based transistors, it was observed that the density of interface states for SiO_2 grown on Si(100) was significantly lower than that observed on Si(111) [28.81–85]. This difference in interface state behavior is attributed to the density of unsatisfied (*dangling*) bonds at the SiO_2/Si interface.

Techniques sensitive to the presence of such point defects, such as electron (paramagnetic) spin resonance (EPR or ESR) [28.88] have provided valuable insight on the atomic nature of the various defects in the bulk and interfacial regions of SiO_2 [28.89–94]. For such defects, although the electrical manifestation of significant densities ($\geq 10^{10}/\text{cm}^2\text{eV}$) of such *trap states* is easily detected by conventional electrical characterization methods, the unambiguous identification of the moiety responsible for the observed electrical behavior is very difficult using only electrical characterization. From techniques like ESR employed over the last 30 years, point-defect structural models have been established in the bulk regions of SiO_2 and Si, as well as at the interface (including various substrate orientations). A schematic illustration of various known point defects for the Si/ SiO_2 system is shown in Fig. 28.16. The major classes of defects that have been examined over the last 35 years by ESR have included interfacial dangling bonds (P_b centers) and bulk defects in SiO_2 (E' centers) [28.91, 94].

The early discovery and study of P_b centers [28.95–97] eventually led to the interpretation of their ESR signals as due to dangling bonds and the realization of their importance to MOS device physics [28.86, 90,

Fig. 28.17 Correlation of mid-gap interface state density with detected spin density from ESR measurements for $\text{SiO}_2/\text{Si}(111)$ and $\text{SiO}_2/\text{Si}(100)$. FP and SP denote *fast* and *slow* pullout conditions for the wafers after thermal treatments. After [28.86, 87], with permission

91, 98]. It has also been noted that P_b -center defects are generated for unannealed, thermally stressed and radiation-damaged MOS structures, and moreover can account for roughly 50% of the density of interface defect states (D_{it}) for Si/SiO₂ interfaces [28.54, 99, 100]. It has been demonstrated that the interface state density can be directly proportional to the density of P_b centers (dangling bonds) for the SiO₂/Si(111) and SiO₂/Si(100) interfaces, as seen in Fig. 28.17. Recently, further ESR work has been performed to establish the detailed structure of the defect on Si(100) and Si(111) [28.101–108].

Mitigation of Defects for Thin SiO₂

Synopses of the early MOS transistor work [28.109–111] examining the importance of the dielectric–semiconductor interface are available [28.6, 43, 112]. Indeed, the close connection between interfacial chemical behavior and electrical device performance was investigated and realized in pioneering surface science work by Law and coworkers on the reaction of gaseous species with atomically clean Ge [28.113] and Si surfaces [28.114–116]. In particular, the relative interface state (dangling-bond) density, as measured by the areal density of surface reactions with technologically important species such as H₂O, H₂, O₂, CO, CO₂, provided important clues on the control of the Si/SiO₂ interface and the resultant electrical properties reported 5–10 years later.

The control of the density of interface defects through the chemical reaction of species, introduced mainly through gaseous exposure at elevated temperatures, has proven to be fruitful. As noted above, early surface science work [28.114] indicated the rapid reaction of H₂ with the atomically clean Si surface. By definition, the atomically clean Si surface is saturated with dangling bonds. The reaction of these bonds with H₂ results in the chemical passivation of the surface – that is, the reaction of the surface to eliminate the dangling bonds and produce a H-terminated Si surface. In the context of the MOS structure [28.47, 117], it was realized early that annealing the structure in ambient H₂ resulted in beneficial transconductance performance [28.118–121]. The use of anneals in forming gas (N₂:H₂ of various mixtures, typically 90–95%N₂:10–5%H₂) were originally developed to improve electrical contacts for the gate and source/drain regions of the MOSFET. Balk and Kooi established the effect of hydrogen ambients on the reduction of fixed charge in the Al/SiO₂/Si MOS structure [28.120, 122].

Subsequent studies demonstrated that anneals of the MOS structure in hydrogenic environments, typically at

400–500 °C for 30–60 min, results in the passivation of dangling bonds at the interface [28.86, 101–106, 123–126].

Hydrogen incorporation into the bulk of SiO₂ can, however, also be detrimental to dielectric performance in MOS capacitors and FETs [28.54, 127]. For example, silicon bonded to hydroxyl (silanol) species have been identified with fixed charge in the oxide, resulting in undesirable, irreversible voltage shifts. This charge induced shift is shown in Fig. 28.18 for n-type and p-type MIS diode structures from their associated capacitance–voltage response [28.1, 6, 7]. (An analogous threshold-voltage shift would be observed in a transistor turn-on characteristic.) More complicated effects such as negative-bias temperature instability (NBTI), where an increase of the density of fixed charge (Q_f) and interface trap (Q_{it}) density is noted with time upon thermal stress and/or under negative bias, has been attributed to H₂O-induced depassivation of Si dangling bonds (i. e., generation of P_b centers) at the Si/SiO₂ interface [28.54, 128]. Defects generated by radiation damage have also been extensively investigated [28.54, 129] as well as interactions with annealing ambients such as vacuum [28.130] or SiO [28.124].

Dielectric Breakdown and Reliability of SiO₂

As noted in Sect. 28.1.2, the reliability of dielectrics is obviously an important phenomenon to control. The scaling of microelectronic devices necessarily results in increased stress on the dielectric due to the higher electric fields placed across the dielectric film. As a result, power-supply voltages are also scaled to minimize the likelihood of catastrophic (*hard*) breakdown, which would generally result in complete failure in the associated integrated circuit. As noted by Hori, such a catastrophic breakdown phenomenon is dependent upon the presence of defects in the dielectric, and thus requires a statistical analysis of many devices (and therefore films) to enable a reliability prediction for the dielectric layer [28.18]. Evaluation of the breakdown is often performed under the conditions of constant-field stress until a time at which breakdown is observed [called time-dependent dielectric breakdown (TDDB)]. Breakdown fields for thermally grown SiO₂ with thicknesses larger than ≈ 10 nm often exceed 10 MV/cm, providing outstanding insulator prosperities for microelectronic applications. Various models have also been developed to accelerate such testing to perform reliability predictions. A concise review of these is offered in the literature as well [28.18, 28]. Defects such as film nonuniformity, bond stress, surface asperities, contam-

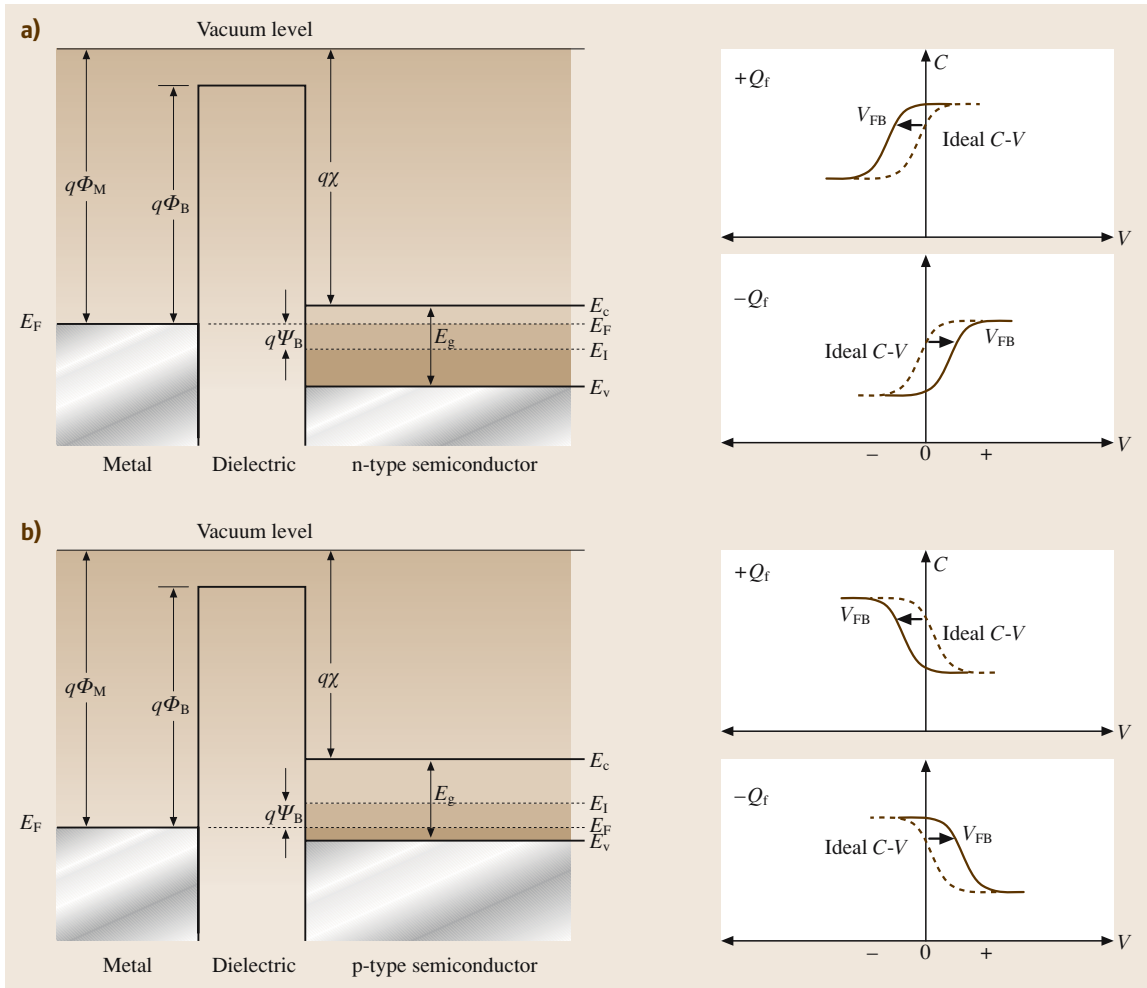

Fig. 28.18a,b The effect of fixed charging of the capacitor dielectric, demonstrating the shift of the associated flat-band voltage for MIS structures with (a) n-type and (b) p-type substrates. After [28.1] (© 2001 AIP, with permission)

ination, and particulates embedded in the film or the Si substrate are a few examples of potential causes of catastrophic breakdown phenomenon.

With the scaling of the SiO_2 gate dielectric layer to thicknesses well below 10 nm, extensive evaluations have been made of the various models that attempt to predict the reliability of SiO_2 in regard to breakdown. Often, a *soft* breakdown can be observed, where the film exhibits a sudden increase in conductivity, but not to the same degree as that observed in hard breakdown phenomenon. In spite of the many years of research on SiO_2 thin films, the nuances of the dependence of voltage acceleration extrapolation on dielectric thickness and the improvement of reliability projection arising

from improved oxide thickness uniformity, have only recently become understood, despite decades of research on SiO_2 [28.131].

28.1.4 Silicon Oxynitride: SiO_xN_y

The introduction of nitrogen in SiO_2 , often described as *silicon-oxynitride* (or more simply SiON) has provided the opportunity to maintain the scaling expectations for integrated circuits while minimizing the process variations associated with the modification of the gate dielectric material [28.18, 40, 71, 132]. (It should be noted that engineers and technologists often loosely refer to SiON films simply as oxide or nitride – frequently lead-

Fig. 28.19 Calculated phase diagram for the growth of Si—O—N for various oxygen partial pressures. After [28.134], with permission

Fig. 28.20 Dependence of permittivity and insulator band gap of SiO_xN_y with SiO_2 content. After [28.135], with permission

ing to confusion on the detailed chemical composition of the film.) Introduction of N into SiO_2 has been accomplished by thermal treatments (in N_2 , N_2O , NO and NH_3) as well as plasma treatments [28.18, 133]. The bulk phase diagram for the SiON system is presented in Fig. 28.19, which indicates that, under equilibrium conditions, $\text{Si}_2\text{N}_2\text{O}$ is the only stable SiON species and SiO_2 and Si_3N_4 would not coexist [28.134]. As noted by Green et al., N would not be expected to incorporate into SiO_2 whenever an even very small partial pressure of oxygen $P_{\text{O}_2} > 10^{-20}$ atm is present. However, the nonequilibrium surface reaction kinetics and/or a reduction in interfacial bond strain likely plays a key role in the tendency for interfacial N incorporation for SiON films [28.40].

The dielectric constant and band gap as a function of the SiO_2 content are presented in Fig. 28.20 [28.135]. As noted in Sect. 28.1.2, it is the increase in the dielectric constant that increases the capacitance of an associated MOS structure. Thus, for a SiON film with $\kappa = 7$, a 2-nm SiON film would ideally exhibit electrical behavior (such as capacitance and leakage-current behavior) equivalent to a 1.1-nm SiO_2 film, according to (28.8). The data in Fig. 28.20 implies that the index of refraction (at 635 nm) varies between $n(\text{SiO}_2) = 1.46$ and $n(\text{Si}_3\text{N}_4) = 2$, indicating that optical techniques such as ellipsometry can provide very useful information for such films.

Like the SiO_2/Si system, point defects have also been studied for SiON films on silicon [28.136]. Lenahan and coworkers examined the role of strain at the interface and the impact on the associated dangling bonds [28.137]. More recently, work on the effects of hydrogen annealing has also examined the SiON system [28.138].

It is also noted that the SiON material system also exhibits useful diffusion-barrier properties. This property is utilized to inhibit uncontrolled dopant diffusion from the polysilicon gate electrode through the dielectric layer and into the channel region of transistors, for example. The formation of SiON films from the reaction of NO or N_2O with Si, as well as nitridation of Si and SiO_2 from N_2 and NH_3 exposure, has been examined in detail and has been summarized in recent reviews [28.40, 71].

For transistor gate dielectric applications, a controlled variation in the depth concentration profile for N is often required throughout the dielectric to maintain the improved device reliability and mobility associated with SiON thin films [28.28]. An example of such N profiles is shown in Fig. 28.21, where a somewhat reduced N content is noted in the vicinity of the Si channel/dielectric interface relative to that near the dielectric/poly-Si gate

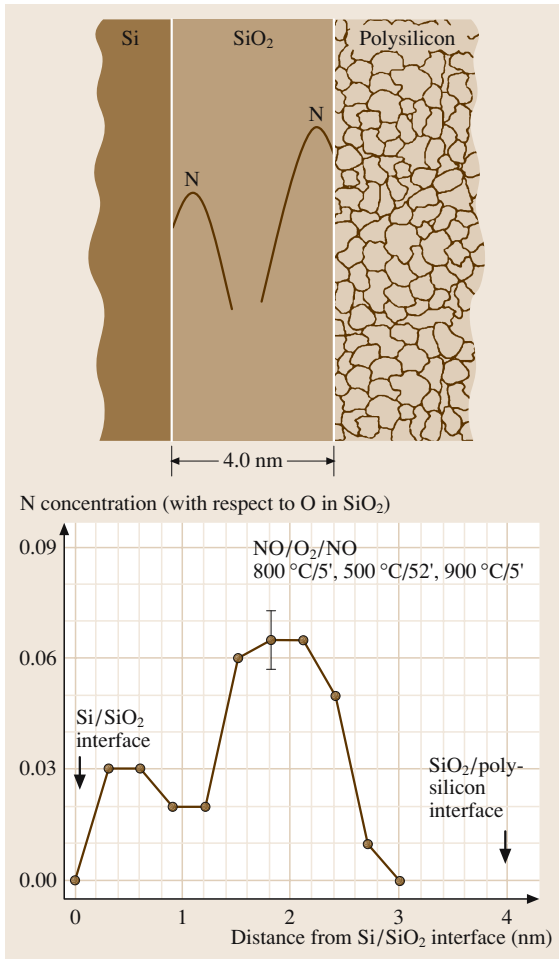

Fig. 28.21 N concentration depth profiles for tailoring the overall dielectric constant and materials properties of a SiON layer. After [28.34] (© 1999 Elsevier, with permission)

interface [28.34]. Such profiles are thought to control effects such as interfacial strain and roughness (which can degrade mobility) and inhibit dopant out-diffusion from the gate electrode. Incorporation of N in thin dielectric films using plasma processes has been studied extensively [28.133, 139–143].

Given the various leakage-current constraints afforded by power limitations and reliability, the scaling of SiON appears to be limited to $t_{eq} \approx 1$ nm, corresponding to the 65-nm node for high-performance microprocessor products set to begin in ≈ 2007 [28.12]. As a result, investigations of alternative high- κ dielectric materials have been initiated over the last several years.

28.1.5 High- κ Dielectrics

Recent research has focused on high- κ dielectrics to further enable scaling of transistor (and memory capacitor) technology. In the context of the industry roadmap, the term high- κ dielectric more generally refers to materials which exhibit dielectric constants higher than the SiON films ($\kappa \approx 7$) described above.

Desirable Properties for High- κ Dielectrics

Many materials systems are currently under consideration as potential replacements for SiO₂ and SiO_xN_y as the gate dielectric material for sub-100-nm (CMOS) technology. It should be stated at the outset that this field of materials research remains very active, and a conclusive summary on the topic of high- κ materials, particularly for conventional MOSFET gate dielectric applications, is not yet possible. The field continues to evolve with interesting research being reported almost weekly in peer-review journals as well as industry newsletters and magazines. Nevertheless, a systematic consideration of the required properties of gate dielectrics indicates that the key desirable properties for selecting an alternative gate dielectric include: permittivity and the associated band gap/alignment to silicon as well as mobility, thermodynamic stability, film morphology, interface quality, compatibility with the current or expected materials to be used in processing for CMOS devices, process compatibility, and reliability. The desirable properties are summarized in Table 28.3. Reviews of the developing field and recent research on high- κ dielectric materials candidates are available [28.1, 2, 144].

Many gate dielectric materials appear favorable in some of these areas, but very few materials are promising with respect to all of these properties. Indeed, many of these desirable properties are interrelated. Many of these materials have been examined over the last 20 years for capacitor applications, for example. Materials currently under extensive investigation include oxides, silicates and aluminates of Hf, Zr, La, Y, and their mixtures, which results in dielectric constants in the range 10–80. Table 28.4 summarizes some of the measured or calculated properties associated with high- κ dielectric material constituents. There are also some recent studies of oxides associated with the rare-earth lanthanide series of elements in the periodic table [28.145]. One notes the tradeoff between the band gap (and therefore the conduction/valence-band offsets to those of Si) for these dielectrics and the associated dielectric constant, as seen in Fig. 28.22 [28.146].

Table 28.3 Desirable properties for high-κ gate dielectrics (65-nm node)

Physical property	Value/Criteria	Electrical property	Value/Criteria
Permittivity	15–25	Equivalent oxide thickness	< 1 nm
Band gap	> 5 eV	Gate leakage current (low power)	< 0.03 A/cm ²
Band offset	> 1.5 eV	Gate leakage current (high performance)	< 10 ³ A/cm ²
Thermodynamic stability to 1000 °C	When in direct contact with Si channel	CV dispersion	Minimal (meV)
Compatibility with metal electrodes	Mimimized extrinsic (pinning) defects	CV hysteresis	Minimal (meV)
Morphology control	Resistance to interdiffusion of constituents, dopants, and capping metals	V _T (V _{FB}) shift (fixed charge, defects, trapping, etc.)	Minimal
Deposition process	Suitable for high-volume production	Channel mobility	Near SiO ₂ universal curve
Etching	Suitable control for patterning after processing/annealing	Interface quality	Near SiO ₂ ; D _{IT} ≈ 5 × 10 ¹⁰ /cm ² eV

The compatibility of alternative dielectrics with metal gate electrodes is also an important consideration [28.1, 3, 147]. The interfacial reactions between some gate electrode metals and gate dielectric is thought to lead to extrinsic states due to Fermi-level pinning, which shifts the threshold voltages for transistors to

a fixed value. Another clear challenge is compatibility with other process steps that entail substantial thermal budgets (≈ 1000 °C, ≤ 10 s) for conventional CMOS. Future scaling may well require a modification (reduction) of such thermal budget desires to incorporate metal gate electrodes in CMOS, and thus may open

Fig. 28.22 Band gap versus dielectric constant for a number of dielectric materials. After [28.146] MRS Bulletin, with permission

the door to the consideration of other gate dielectric materials that exhibit stability at somewhat lower temperatures. However, key issues that must be addressed under such a scenario include alternative source/drain engineering (e.g. dopant activation at lower thermal budgets) and/or gate electrode formation in the device fabrication flow (e.g. gate electrode insertion after high-temperature anneals). Previous research on such CMOS process modifications has indicated that a variety of challenges exist to address such scenarios with adequate process margin and yield.

Mobility Degradation for Transistors with High- κ Dielectrics

In the case of many of the alternate gate dielectric materials (mainly metal oxides) currently under consideration, the polarizability of the metal–oxygen (*ionic*) bond is responsible for the observed low-frequency permittivity enhancement. Such highly polarizable bonds are described to be *soft* relative to the less polarizable *stiff* Si–O bonds associated with SiO₂. Unlike the relatively stiff Si–O bond, the polarization frequency dependence of the M–O bond is predicted to result in an enhanced scattering coupling strength for electrons with the associated low-energy and surface optical phonons. This scattering mechanism can therefore degrade the electron mobility in the inversion layer associated with MOSFET devices. A theoretical examination of this effect is provided by Fischetti et al. where calculations

of the magnitude of the effect indicate that pure metal–oxide systems, such as ZrO₂ and HfO₂, suffer the worst degradation, whereas materials which incorporate Si–O bonds, such as silicates, fare better [28.160]. In that work, it is also noted that the presence of a thin SiO₂ interfacial layer between the Si substrate and the high- κ dielectric can help boost the resultant mobility by screening this effect, although the maximum attainable effective mobility is still below that for the ideal SiO₂/Si system. These researchers further suggest that the effect is also minimized by the incorporation of Si–O in the dielectric, as in the case of pseudo-binary systems such as silicates.

Comparisons of this model with experimental evidence have recently been reported explicitly through the comparison of HfO₂ and Hf–silicate mobility studies. The results indicate that n-MOS and p-MOS poly-Si gated devices with Hf–silicate dielectrics exhibit better mobilities (approaching those of SiO₂) over those obtained using HfO₂ due to a diminished soft-phonon scattering mechanism [28.161]. Incorporation of metal gate electrodes results in further improvement [28.162].

Current High- κ Dielectric Research and Development

At this time (end of 2004), work on Hf-based dielectric materials, mainly Hf–silicates [28.163] and HfO₂ [28.1], dominates the recent engineering literature (Fig. 28.23) and they appear to exhibit useful properties for integrated-circuit scaling down to the 20-nm node. These properties include a relative stability for interfacial reactions that prefer silicate formation thus can avoid a lower overall dielectric constant of the high- κ dielectric stack, due to a pure SiO₂ interfacial layer, as described by equation (28.9). The papers on these materials systems are too numerous to list individually here and so the reader is referred to the reviews on the topic [28.1, 2, 144].

Of particular importance for gate dielectrics have been investigations of the stability (in particular, changes in morphology and interdiffusion) of these films upon thermal processing in view of the required integration constraints for CMOS applications [28.3]. A significant hurdle for the integration of all dielectrics currently under consideration for conventional CMOS is the stability of all gate-stack constituents (stable film morphology, minimal interdiffusion, etc.) under a thermal budget of $\approx 1000^\circ\text{C}$ for 10 s for dopant activation and adequate process integration margin. Under such thermal treatments, gate dielectric constituents such as Zr [28.164] or Al [28.165] have been reported to penetrate the Si chan-

Fig. 28.23 Distribution of papers presented at recent IEEE international electron devices meeting (IEDM) and very-large-scale integration (VLSI) conferences indicate the current emphasis of materials systems examined for gate dielectric research

nel region and thus present a potential source of impurity scattering for mobility degradation. In contrast, Hf does not appear to exhibit such penetration within detectable limits [28.166].

It is also important to note that most of the high- κ metal oxides listed in Table 28.4 crystallize at relatively low temperatures ($T \approx 500\text{--}600^\circ\text{C}$). An exception is Al_2O_3 where crystallization in thin films is observed at $T \approx 800^\circ\text{C}$ [28.167]. In the case of Hf-silicates, film morphology (viz. suppression of crystallization) and diffusion-barrier properties can be controlled through the incorporation of N, as in the case of SiO_2 [28.157, 168–172]. Currently, HfSiON dielectrics appear to provide desirable properties in this regard.

Suppression of crystallization is also observed for aluminates (depending upon the Al content) [28.173], but there are fewer studies of interdiffusion with the Si substrate available at this time. As noted above however for the case of Al_2O_3 thin films, Al penetration into the Si substrate has been reported upon thermal annealing budgets appropriate for dopant activation [28.165]. Such

Fig. 28.24 Contours of constant scale length, which is proportional to the transistor gate length, versus dielectric constant and insulator thickness, showing the useful design space for high- κ gate dielectrics. Data points are rough estimates of the tunneling constraints for various high- κ insulators. The depletion depth is assumed to be 15 nm. The useful design space will shrink with decreasing depletion depth. After [28.23] (© 2004 IEEE, with permission)

penetration could be a concern for any high- κ dielectric incorporating Al as well.

The morphology of the dielectric film may also impact on the propensity for capping layer constituents (from metal gate material layers) to diffuse through the stack as well. Metal gate materials currently under investigation include well-known minority-lifetime killers such as Ni (in NiSi) as well as tunable-work-function alloys and layers [28.3, 147, 174, 175]. The potential for the interdiffusion of metals into the channel region is clearly undesirable.

The limits of a useful high- κ dielectric constant value have also been examined. For example, the study by Frank et al. (Fig. 28.24) suggests that there exist a range of useful permittivity values as planar CMOS transistor structures are scaled [28.23]. It is noted that the physical thickness of the gate insulator should be less than the Si depletion length under the channel region, and that this results in a limited design space that enables further device scaling. Again, one notes that the dielectric constant cannot be arbitrarily increased without careful consideration of the complete transistor design.

28.2 Isolation Dielectrics

Dielectrics are also employed to electrically isolate various regions of an integrated-circuit technology. The dominant material for these applications is SiO_2 . A method commonly employed to obtain such isolation in larger-scale IC technologies (generally with gate lengths larger than $0.25\text{ }\mu\text{m}$) is the so-called local oxidation of silicon (LOCOS) technique, where regions of Si between various components are preferentially (thermally) oxidized [28.18, 28]. Such isolation oxides are typically several hundred nanometers thick and the tapered shape of the edge of the LOCOS isolation oxide near the transistor gate dielectric and source/drain region (often referred to as the *bird's beak*) is an important region to control during the device fabrication at these gate lengths. Thinning of the dielectrics in this region results in breakdown reliability concerns, as the electric fields in this region can be quite high. A *reoxidation process* is often performed to improve the thickness and reliability of the SiO_2 in this region as well.

Scaling ICs beyond this gate-length regime however has required the placement of isolated regions utilizing deposited SiO_2 trench structures, as seen in Fig. 28.6. As summarized by Wolf, extensive work has been done to control the shape of the trench walls and the SiO_2 layer initially formed on these walls. Chemical vapor deposition methods are normally utilized for the dielectric deposition as this approach provides superior conformality in the trench structure. Filling the trench without void formation, controlling film stress, and chemical mechan-

ical polishing properties are also important aspects that must be addressed in the fabrication process [28.12, 28]. Scaling of integrate circuits will result in a decrease of the area available for these isolation trenches, and so the increasing aspect ratio of the trench depth to width requires considerable attention in regard to trench filling. The control of the shape of the top corner regions of the trench structures is also an area of concern due to high-field reliability as well as the formation of essentially a parasitic *edge transistor*. Initially, thermal oxidation methods were employed to round off the shape of the corner, but further scaling will require etch processing methods.

The fabrication of transistor source/drain regions utilizing implantation processes also utilizes a dielectric spacer layer that surrounds the transistor gate region (Fig. 28.6). This spacer provides isolation between the gate and source/drain regions, and also permits the control of the depth (and therefore profile) of the implanted dopant species – a so-called self-aligned dopant implantation process. Dielectrics used for spacer technologies include deposited SiO_2 and Si_3N_4 , and the extent of the spacer dimensions from the gate is an important device parameter to control [28.18]. Further scaling of transistor structures will likely result in the need for elevated source/drain regions, and so process compatibility of the spacer material with the source/drain formation processes and high- κ dielectrics will become an important consideration [28.12].

28.3 Capacitor Dielectrics

Capacitors are employed in a variety of integrated circuits including storage (memory) circuit elements and input/output coupling circuitry. Clearly, dielectrics are critically important in this application. In contrast to the MIS structure associated with transistors, capacitors are passive devices incorporating a metal–insulator–metal (MIM) structure. Early electrodes were composed of degenerately doped Si while more recent work focuses on integrating metals for modern devices.

28.3.1 Types of IC Memory

A dominant memory technology for the IC industry includes dynamic random-access memory (DRAM) in which capacitors play the essential role of storing charge,

and thereby useful information. This type of memory element requires refreshing in order to maintain useful information, and the rate of refresh is fundamentally related to the dielectric associated with the capacitor structure and leakage of charge from that capacitor. As a result, this class of memory devices is called volatile. In contrast, a static random-access memory (SRAM) nonvolatile memory element required a capacitor which stores charge without the refresh requirement, and can preserve charge for many years. Again capacitor design must include the consideration of the dielectric [28.27].

In addition to DRAM capacitors, other types of capacitors are used in the back end of the transistor flow. These devices are MIM capacitors, and they typically reside between levels of metal interconnects, and

serve as decoupling or radio-frequency (RF) capacitors for input/output functions. For these applications, the capacitance density is still of critical importance, but other factors must be considered, such as the linearity of the capacitance as a function of voltage and temperature.

28.3.2 Capacitor Dielectric Requirements in View of Scaling

In brief, scaling the capacitor dimensions requires a tradeoff between the amount of stored charge required for a reliable memory element and the area occupied by the capacitor (and the associated transistors for the memory cell). From generation to generation of devices, the amount of stored charge is kept roughly constant (≈ 30 fF/cell), even though dimensional scaling occurs, for bit detection (sense amplifier), retention and reliability reasons [28.28, 176].

As noted in (28.6) for a simple parallel-plate capacitor, the area associated with the capacitor as well as the dielectric permittivity play an important role. Maintaining the required capacitance with scaling was (and will be) accomplished by increasing the capacitor area, for a suitable dielectric thickness where leakage currents are severely limited; this can be accomplished by utilizing three-dimensional capacitor structures produced in the Si bulk, such as deep-trench capacitors [28.176, 177]. Clever and intricate processing methods to increase the capacitor area were adopted for several generations for well-established SiO_2 and Si–oxynitride dielectric capacitor materials, such as the implementation of hemispherical-grain (HSG) poly-Si and *crown* structures (Fig. 28.25). Eventually, practical

concerns about cost and device yield make manufacturing such structures problematic. Thus, substantially increasing the dielectric constant of the insulating material was considered, and less-complicated structures can be fabricated. At this point, both stacked and trench capacitor structures are dominant in the industry. Indeed, the ability to fabricate deep-trench structures will help guide the need for the incorporation of alternative dielectrics. These structures often require the use of chemical vapor deposition (CVD) methods to ensure conformality over the stacked structure topography or deep within trenches that have large aspect ratios. More recently, atomic-layer CVD processes have been examined for this purpose as well. Although capacitors do not have requirements regarding lateral transport of carriers, as transistors do, capacitors have much more rigorous charge-storage-capacity requirements when they serve as memory elements. This additional constraint results in projected limitations.

28.3.3 Dielectrics for Volatile Memory Capacitors

Capacitor dielectric properties for dynamic random-access memory (DRAM) applications have been important since these devices were introduced commercially in the early 1970s for volatile memory [28.178]. *Fazan* provides some rules of thumb that provide guidance for the selection of desirable materials (and electrical) properties for DRAM capacitor dielectrics [28.176]. In addition to the desire to maintain the storage capacitance around 30 fF/cell, leakage of charge from the storage capacitor must be kept to a cur-

Fig. 28.25 Assorted capacitor structures employed in IC technology. Courtesy of S. Summerfelt

rent density of less than $0.1 \mu\text{A}/\text{cm}^2$ so that less than $\approx 10\%$ of the capacitor charge is lost during the associated refresh (recharge) cycle. Scaling the DRAM cell size has resulted in the consideration of a variety of dielectric materials [28.12, 27, 28].

SiO_2 and SiO_xN_y

The earliest DRAM planar capacitors utilized SiO_2 as the dielectric. Subsequent scaling into the Mbit regime required an increased capacitance density, and thus a higher dielectric constant. So-called oxide/nitride (ON) or oxide/nitride/oxide (ONO) dielectric stacks were incorporated [28.18]. As the names imply, the dielectric consisted of a stack of SiO_2 and Si_3N_4 layers. The incorporation of the Si nitride layer, typically by a deposition method such as chemical vapor deposition, results in an overall increase in the dielectric constant of the stack. Scaling the stacked capacitors has required the development of alternative dielectrics (Al_2O_3 and Ta_2O_5) at the 130-nm node. Nevertheless, according to the 2003 ITRS, Si_3N_4 will be utilized for DRAM capacitor structures to the 45-nm node.

Al_2O_3

Aluminium oxide exhibits a dielectric constant of $\kappa \approx 9$ and a significant band gap of 8.7 eV, as noted in Table 28.4. However, the rate of capacitor scaling and the charge storage per cell appears to require a dielectric constant significantly larger than this value. As a result, substantial research and development was also conducted to incorporate tantalum pentoxide into DRAM capacitor dielectrics. According to the 2003 ITRS, Al_2O_3 will be utilized for DRAM capacitor structures to the 45-nm node.

Ta_2O_5

Amorphous tantalum pentoxide provides a dielectric constant of $\kappa \approx 25$ with a concomitantly smaller band gap (≈ 4.4 eV). Ta_2O_5 films are often deposited by CVD processes for conformality in stacked or trench capacitor structures. Metal–insulator–metal structures are required to preserve the maximum capacitance density, as reactions with polysilicon results in the formation of a thin SiO_2 layer as discussed above in connection with gate dielectric materials. Moreover, the use of MIM structures permits the possibility of a Ta_2O_5 crystalline microstructure, which enables a $\kappa \approx 50$. Chaneleire et al. has summarized the research and development associated with Ta_2O_5 films [28.179]. According to the 2003 ITRS, Ta_2O_5 will also be utilized for DRAM capacitor structures to the 45-nm node.

Barium Strontium Titanate (BST)

Considerable effort has also been exerted in the search for CMOS-compatible “ultra high- κ ” dielectrics. Such materials are envisioned to be required for scaling at and beyond the 45-nm node [28.12]. CVD BST films have been a focus of these efforts in the recent past, with a dielectric constant of $\kappa \approx 250$. The movement of the Ti atom (ion) in the BST lattice structure results in a substantial contribution to the polarization of this materials system. Utilization of this material has required the use of noble-metal electrodes including Pt, Ru (RuO_2) and Ir to control interfacial reactions. As a result, considerable process complexity is introduced into the manufacturing process.

Alternative Dielectric Materials

We also note that recent research on alternative gate dielectric materials, such as HfO_2 and HfSiO , has also rekindled interest in these materials for capacitor applications. The prospect of better interfacial oxide formation control has been one motivating factor, although substantial further work is still required.

28.3.4 Dielectrics for Nonvolatile Memory

As the name implies, nonvolatile memory devices retain their state whether power is applied to the device or not. A thorough description of such devices is provided by Hori [28.18]. For example, the electrically erasable programmable read-only memory (EEPROM) device requires an erase operation prior to programming (*writing*) new data to the device. To accomplish this, a stacked-gate MOS structure is utilized where the intermediate gate is embedded in a dielectric – a so-called *floating gate*. The placement of a higher electric field to permit Fowler–Nordheim tunneling through such dielectrics to the floating gate is utilized to program arrays of these elements – called *flash memory*. Scaling and the reliability required for such nonvolatile memory devices has required the evolution from using SiO_2 to SiO_xN_y .

SiO_2 and SiO_xN_y

For flash memory elements, the formation of nitrided SiO_2 enables a suitable dielectric for reliable operation. The nitridation process, as described earlier, entails the exposure of an SiO_2 dielectric to anneals with N_2 , NH_3 , or N_2O (or combinations of these), often under rapid thermal annealing conditions. Details of this process have been summarized by Hori [28.18]. Subsequent reoxidation of the dielectric is also employed to improve reliability properties.

So-called silicon oxide nitride oxide silicon (SONOS) structures are under examination to improve the scaling limitations of the dielectric thickness and tunneling properties [28.180].

Further scaling of transistors presents significant challenges for flash memory. The thickness of the dielectric is again a key constraint given the need for reliable operation under high-electric-field conditions. Memories based on Si nanocrystals embedded within SiO_2 are currently under development to address this challenge [28.182].

Ferroelectrics

Ferroelectric materials, such as $\text{PbZr}_{1-x}\text{Ti}_x\text{O}_3$ (PZT) or $\text{SrBi}_2\text{Ta}_2\text{O}_9$ (SBT) have been examined for some time as potential dielectric candidates for memory elements based upon the ferroelectric effect [28.26]. In storage capacitors incorporating such materials, the polarization state of the ferroelectric is preserved (once poled) without the presence of an electric field [28.25]. This state is then sensed by associated circuitry and can therefore be used as a memory device.

Principles. Ferroelectricity describes the spontaneous alignment of dipoles in a dielectric as the result of an externally applied electric field. This alignment behavior has thermal constraints in that heating the dielectric above the Curie temperature results in a phase transformation to a paraelectric state. Therefore, capacitors and circuits which utilize the ferroelectric effect must contain materials that have a relatively high Curie temperature compared to that experienced during operation and reliability testing (generally $> 200^\circ\text{C}$). As shown in Fig. 28.26, the polarization response of these materials to an externally applied electric field exhibits a hys-

Fig. 28.26 Polarization-voltage curve for a ferroelectric material. After [28.181] (© 2004 IEEE, with permission)

teresis behavior [28.181]. (This behavior is analogous to that observed in ferromagnetic materials, hence the name. Note however that ferroelectric materials contain no iron.) Upon increasing the voltage across the ferroelectric above a coercive value (V_c), the polarization of the material is limited to the spontaneous value (P_s), corresponding to maximum domain alignment. Removal of the electric field results in a decrease of the polarization to the remnant value (P_r), which can be sensed accordingly. The time required for the polarization to be switched is on the order of nanoseconds for these devices. Moreover, this can be accomplished in low-power circuits, making these materials attractive, in principle, for scaled CMOS.

Materials. In addition to the perovskite PZT and SBT materials mentioned above, other materials investigated for nonvolatile memory applications include BaTiO_3 , PbTiO_3 , $\text{Pb}_{1-x}\text{La}_x\text{Zr}_{1-y}\text{Ti}_y\text{O}_3$ (PLZT), $\text{PbMg}_{1-x}\text{Nb}_x\text{O}_3$ (PMN), $\text{SrBi}_2\text{Nb}_2\text{O}_9$ (SBN), and $\text{SrBi}_2(\text{Ta}_{1-x}\text{Nb}_x)_2\text{O}_9$ (SBTN). These materials generally have the cubic structure ABO_3 shown in Fig. 28.27, with the larger (A) cations in the corner of the cubic unit cell, and the smaller (B) cations (e.g. Ti, Zr, Mg, Nb, Ta) located in the center of the unit cell. The oxygen anions are located at the face-centered-cube positions. The distortion of the unit cell in response to the externally applied electric field results in the observed polarization. In particular, the movement of the B cation (e.g. Ti) in the associated lattice between the equilibrium

Fig. 28.27 Perovskite ABO_3 unit cell showing motion of the B ion in the cell among the equilibrium positions, resulting in ferroelectric polarization behavior. After [28.181] (© 2004 IEEE, with permission)

positions results in substantial distortion and therefore polarization [28.26, 181].

Issues for Ferroelectric Materials. Substantial research is underway to understand the reliability issues associated with ferroelectric memory devices. The retention of the polarization state is one area of investigation. It is observed that the polarization state decreases slowly over time (*log-time* decay behavior), even in the absence of an electric field, and the reasons are still poorly understood. Another area of concern is *imprint*, where a polarization state, if repeatedly poled to the same state, becomes preferred. Subsequent switching to the opposite state can result in relatively poor retention times. Again, the physical mechanism associated with this phenomenon is poorly understood. The role of hydrogen exposure is another area of investigation, where exposure of ferroelectric random-access memory (FeRAM) elements to hydrogen, commonly from forming gas during CMOS back-end processing, can result in the suppression of

the remnant polarization [28.183–185]. Barriers for hydrogen permeation into the ferroelectric are an area of investigation as well.

Phase-Change Memory

An alternative to charge-storage devices, based upon a controlled phase change, is also now under consideration for scaled integrated circuits [28.186]. Chalcogenides, such as GeSbTe, have been utilized in compact-disk memory storage technology. In that technology, a laser heats a small volume of the material, resulting in a phase change between crystalline and amorphous states, which obviously changes the reflectivity of the exposed region. For the IC application, an electric current is passed through these materials to accomplish the phase-change effect, dramatically altering the resistance of the region. This utilization of alternative (non-dielectric) material is another example of new directions under consideration for IC scaling.

28.4 Interconnect Dielectrics

As noted in Fig. 28.1, the performance of the integrated circuit, as measured by the time delay for signal propagation, also depends upon the interconnections between circuit elements. The scaling of CMOS has resulted in a substantial increase in interconnect metal lines throughout the IC chip, which make a major contribution to the delay time. The industry segments these levels into *local* (interconnection between neighboring devices), *intermediate* (metal 1 interconnection between neighboring circuits), and *global* (interconnection across the chip), as shown in Fig. 28.28. A cross section of a contemporary 65-nm-node IC is shown in Fig. 28.29 where eight layers of metallization and the associated dielectric isolation are evident.

As discussed in Sect. 28.0.1, the *RC* time delay for the interconnect contribution to performance can be attributed to the metal lines and their isolation dielectrics (see Fig. 28.1). The resistivity of the lines has been reduced in the industry by recently adopting copper metallization processes in lieu of aluminium metallization in 1998. Further reductions in the delay time then require the consideration of the dielectric between the lines, as these essentially form a parasitic capacitor structure, and therefore low- κ dielectrics are required. It is noted that for the global interconnect level, new concepts such as RF or optical communication, will likely be needed for continued CMOS scaling.

28.4.1 Tetraethoxysilane (TEOS)

For many years, CVD-deposited SiO₂ provided adequate isolation for interconnection of ICs. This was frequently accomplished through the deposition of tetraethoxysilane (TEOS) and subsequent densification thermal treatments to render a dielectric constant of $\kappa \approx 4$. Films produced in this manner were relatively easy to process and provided good mechanical strength. The incorporation of fluorine into these films [fluorinated silicate glass or (FSG)] succeeded in a reduction of the dielectric constant to $\kappa \approx 3.5$ – 3.7 after considerable efforts. As F is among the most electronegative elements, the incorporation of F into the silica matrix renders the film less polarizable due to Si–F bond formation, and therefore results in a lower permittivity. Scaling CMOS however has driven the industry to consider interconnect dielectric materials with $\kappa \ll 4$.

28.4.2 Low- κ Dielectrics

As seen in Figures 28.28 and 28.29, several levels of dielectrics must be incorporated with the metallization schemes associated with ICs. As can be seen, dielectrics utilized in this back end of (fabrication) line (BEOL) portion of the IC fabrication process are also segmented into pre-, inter- and intra-metal dielectrics. Addition-

Fig. 28.28 Schematic of a typical chip cross section showing key interconnect metallization and dielectric layers. From [28.12]

ally, dielectric layers are employed to facilitate etching control for Cu metal patterning of the various interconnection lines. This requires materials integration with barrier layers (that control Cu diffusion), etch stop layers, CMP (chemical mechanical polishing) stop layers as well as overall mechanical stability. Additionally, for the local and metal 1 layers, the future incorporation of metal gate and/or NiSi materials may require extensive limitations on processing temperatures ($< 500^{\circ}\text{C}$).

Several materials are under investigation for the low- κ application, and some of these are summarized in Table 28.5 [28.12, 28]. Most consist of polymeric (low-Z) materials with varying porosity

Fig. 28.29 Cross section of a modern IC chip for the 65-nm node to be in production in 2005 showing eight levels of metal interconnects isolated by low- κ dielectrics. (Courtesy of Intel)

to enable a sufficiently low dielectric constant for interconnect applications. Recent technology announcements for the 90-nm and 65-nm nodes often refer to these materials as carbon-doped oxides [28.187, 188]. At this point, films are deposited by either CVD or spin-on methods. Desirable properties for low- κ dielectrics include thermal stability (to $\approx 500^{\circ}\text{C}$), mechanical stability (to withstand packaging), electrical isolation stability/reliability (similar to SiO_2), chemical stability (minimal moisture absorption, resistance to process chemicals, resist compatibility), compatibility with BEOL materials (e.g., diffusion barriers) and processes (etching, cleaning, post-metallization and forming-gas anneals, chemical mechanical polishing, etc.) and of course low cost. As noted by Wolf, thermal properties of low- κ materials are important

Table 28.5 Interconnect dielectric materials (after [28.12, 28])

Dielectric constant	Material	Pre-production year
3.5–3.7	FSG	Current
3.0–3.6	Polyimides	Current
2.7–3.1	Spin-on glass	Current
2.6–2.9	Organo-silicate glasses (OSG)	Current – 2011
2.6–2.8	Parylene-based polymers	Current
2.5–3.2	Methyl/hydrogen silsesquioxane (MSQ/HSQ)	2005
1.8–2.4	Porous MSQ, parylene-based polymers	2008
1.1–2.2	Silica aerogels	2011
1.5–2.2	Silica xerogels	2011

for effective power dissipation in high-performance applications.

According to the ITRS roadmap, deposited silicon oxides are envisioned to be employed for pre-metal dielectrics through the 45-nm node (≈ 2012). The introduction of Ni-silicide contacts, metal gate electrodes and high- κ dielectrics will certainly have an impact on the development of alternatives to these deposited oxides. Methyl/hydrogen silsesquioxane (MSQ/HSQ) appear to be under consideration for further development in this regard.

28.5 Summary

It should be evident that IC technology is critically dependent upon suitable dielectrics throughout the entire chip. Materials properties, and their resultant electrical properties, must be carefully evaluated throughout the research and development process associated with integrated circuit technology.

For inter/intra-metal dielectrics, a wide array of materials are envisioned, as seen in Table 28.5. Both FSG and organo-silicate glasses (OSG) are envisioned to address the requirements of these interconnect dielectrics to the 45-nm node. Thereafter, alternative materials ($\kappa < 2.8$) mentioned in Table 28.5 will need to be developed.

Patterning (hard mask) and etch-stop dielectrics will continue to employ Si-oxides, Si-nitrides, Si-oxycarbides, and Si-carbonitrides to the 45-nm node. Thereafter, alternative materials for patterning may be required.

Recent years and roadmap predictions clearly place an emphasis on the development of new materials for the various dielectrics employed to achieve scaling. Researchers and technologists engaged in this endeavor must be able to span several disciplines to enable the successful integration of these new dielectric materials.

Thin Films

29. Thin Films

This chapter provides an extended introduction to the basic principles of thin-film technology, including deposition processes, structure, and some optical and electrical properties relevant to this volume. The material is accessible to scientists and engineers with no previous experience in this field, and contains extensive references to both the primary literature and earlier review articles. Although it is impossible to provide full coverage of all areas or of the most recent developments in this survey, references are included to enable the reader to access the information elsewhere, while the coverage of fundamentals will allow this to be appreciated.

Deposition of thin films by the main physical deposition methods of vacuum evaporation, molecular-beam epitaxy and sputtering are described in some detail, as are those by the chemical deposition methods of electrodeposition, chemical vapour deposition and the Langmuir–Blodgett technique. Examples of structural features of some thin films are given, including their crystallography, larger-scale structure and film morphology. The dependence of these features on the deposition conditions are stressed, including those required for the growth of epitaxial films and the use of zone models in the classification of the morphological characteristics. The main optical properties of thin films are reviewed, including the use of Fresnel coefficients at

media boundaries, reflectance and transmittance, matrix methods and the application of these techniques to the design of antireflection coatings, mirrors and filters. The dependence of electrical conductivity (or resistivity) and the temperature coefficient of resistivity in metallic thin films is discussed, in particular the models of Thomson, Fuchs–Sondheimer and the grain-boundary model of Mayadas–Shatzkes. For insulating and semiconducting thin films the origin and effects of several high-field conduction processes are examined, including space-charge-limited conductivity, the Poole–Frenkel effect, hopping, tunnelling and the Schottky effect. Finally, some speculations regarding future developments are made.

The earliest use of thin films by mankind is probably in the application of glazes to brickwork and pottery. Tin glazing was discovered by the Assyrians and was used to coat decorative brickwork. Glazed brick panels have been recovered from various archeological sites, with a fragment from Nimrud being dated to about 890 B.C. Various alternative types of glaze have since been developed, and are used both to overcome the effects of porosity in pottery and for decorative purposes. The importance of thin films in optics was first recognised in the 17th century by Hooke, Newton and others. In 1675

Newton described observations of colours in thin films of transparent material and from geometrical considerations was able to calculate effective film thickness and correlate this with the periodicity of observed colours. The films in question were typically of air or water in the space between two glass surfaces having different radii of curvature. The phenomena described are seen most conveniently as *Newton's rings*, where an optically flat glass surface is in contact with a convex glass surface having a large radius of curvature. Under monochromatic illumination in reflection, a series of concentric

coloured rings were observed, the radii being proportional to $\sqrt{1}$, $\sqrt{2}$, $\sqrt{3}$, etc. Although the wave nature of light and interference phenomena were not universally accepted at that time (especially by Newton) these observations, and others where the radii of the rings were seen to be larger for red than for violet light, established one of the most important properties of thin films. Since these early observations of thin film properties, they have been found to display not only characteristic and distinctive optical behaviour, but also mechanical, electrical and magnetic properties. These properties underpin many of their present-day industrial applications, such as antireflection coatings and optical filters, surface acoustic wave devices, electronic components (both discrete and integrated) such as resistors, capacitors, thin-film transistors and other active devices, magnetic data storage and superconductors.

Notwithstanding this wide range of properties and applications, it should be stressed that there is no watertight definition of the thickness below which a film becomes thin. The reason for this is primarily because different properties scale differently with thickness. *Eckertová* [29.1] has pointed out that it is permissible to say in general that the physical limit is determined by the thickness below which certain described anomalies appear, but that this differs for different physical phenomena. For instance a film which is optically thin may be of the order of the wavelength of light (≈ 500 nm) although some electrical properties are determined by the mean free path of conduction electrons (≈ 50 nm for metals) or by the thickness at which a given applied voltage produces an electric field which leads to high-field (nonlinear) behaviour. Generally speaking a thin film has a thickness of less than $1\text{ }\mu\text{m}$, and is deposited on the surface of a substrate by one of several distinct deposition methods [29.2]. In keeping with the remit of this Handbook, the emphasis in this chapter is on the electrical and optical properties of thin films, as these are clearly the most important in the field of electronic and optoelectronic materials. It is not the intention to dismiss thermal and mechanical properties as irrelevant in this sphere, but to stress that, although they may both also have an influence on the electrical and optical properties, they are both mainly dependent on the material itself. Mechanical properties of thin films have been reviewed by *Hoffman* [29.3] and also by *Campbell* [29.4]. However, the *structure* of thin films often has a crucial effect in determining other thin-film properties and, unlike the thermal and mechanical properties, is very largely determined by the film deposition method and conditions. For these reasons sections on both the struc-

ture and deposition methods of thin films are included in this review.

The basic structure of the chapter, following this brief introduction, covers the various aspects of thin films starting from their deposition methods, through their structures to their optical and electrical properties. There is no attempt to cover all of these aspects comprehensively; in a chapter such as this there is sufficient space to cover only the most important techniques and properties. In Sect. 29.1 the major deposition methods are described, such as physical processes like evaporation and sputtering, and chemical methods including chemical vapour deposition (CVD) and the Langmuir–Blodgett technique for molecular films. In Sect. 29.2 some examples of the crystalline structure of various types of films are examined. These can be relatively simple in the case of evaporated metal films, whereas compound films (such as compound semiconductors) can exhibit a variety of different structural forms depending on the deposition conditions and the thickness. Films prepared from larger molecules, such as the organic phthalocyanines having molecular weights of the order of 500, can also show several quite complex structures. In addition to the crystal structure per se, which is normally determined using X-ray, electron or neutron diffraction techniques, the morphologies of thin films often show interesting features, which are observed using electron microscopy or one of the newer scanning-probe imaging techniques such as scanning–tunnelling microscopy (STM) or atomic force microscopy (AFM). Section 29.3 covers the basic optical and electrical properties of thin films. The optical properties covered in Sect. 29.3.1 are largely the result of the electromagnetic wave nature of light, leading to the interference phenomena which were first observed in the 17th century. Films of suitable thickness and refractive index may be used in simple antireflection coatings, and quite complex multilayer film structures are used as optical filters. In Sect. 29.3.2 electrical properties are described. These include electrical conductivity (or resistivity) in relatively high-conductivity materials such as metals, where the conductivity depends not only on the carrier concentration and bulk mean free path, but is also modified by the effects of scattering at one or both of the film surfaces and internal grain boundaries. Lateral conduction in discontinuous (island) films where there are significant potential barriers between highly conducting regions has been investigated by *Neugebauer* and *Webb* [29.5], although this not discussed in the present work. This mechanism is reviewed elsewhere in the literature [29.1, 6]. Various nonlinear conduction pro-

cesses arise as the result of the high electric fields that can be applied across thin films; for example a film of thickness 100 nm having a potential difference of only 1 V applied between its surfaces, would experience a field of 1×10^7 V/m, which approaches the dielectric breakdown strength of many materials. Finally in Sect. 29.4 the main points of the discussion are summarised and some speculations concerning future trends are given.

Much of the technology associated with thin-film deposition and growth is explicitly excluded from this discussion. The measurement of film thickness, both during deposition (monitoring) or post-deposition, is not covered, although good accounts are given in the literature [29.7, 8]. Furthermore the condensation and growth mechanisms of thin films are also omitted [29.9, 10], although the structure and other properties are largely influenced by these. Many of the up-to-date materials properties and device applications are covered elsewhere in this volume. The reader is referred to Chapt. 14 for details of epitaxial growth techniques and to Chapt. 17 for structural characterisation. Optical properties and characterisation are discussed in Chapt. 3, while the corresponding materials and devices are addressed in Chapt. 37. Sensors and transducers, which are frequently based on various thin-film techniques (both inorganic and organic) are described in Chaps. 39 and 54. In the area of electronics, much current effort is in the areas of molecular electronics as described in Chapt. 53. Indeed the present author has predicted that many of the high-field conduction effects commonly observed in thin films will, in due course, also be detected in nanostructures in a suitably modified form [29.11].

Many of the topics covered in this chapter are explained in more detail in various books. The *Handbook of Thin Film Technology* [29.12], although published over three decades ago, has an enormous amount of detail concerning basic thin-film phenomena, most of which is still of interest today. Another very useful resource is the series of volumes originally entitled *Physics of Thin Films* and later simply *Thin Films* (recent volumes retitled *Thin Films and Nanotechnology*) published by Academic Press. Volume 25 of this series [29.13] contains an index for all the earlier volumes covering the years 1963–1998. Detailed references to several articles from both these sources are given in the references. Also of particular interest in the materials field is the *Handbook of Thin Film Materials* [29.14]. The reader is also referred to several other books covering the general field of thin films and technology [29.1, 15–19]. Other books covering more restricted areas of thin-film technology (e.g. optical properties, electronics) are referred to in the appropriate sections.

The SI system of units is used throughout, and where original work was presented in non-SI units, these have normally been converted. Other customary units, such as the electronvolt, are used where appropriate. The main emphasis in this chapter is on the physics of the deposition processes and the optical and electrical properties, and on their relationships with film structure, while keeping mathematical details to a minimum. As mentioned earlier, only the most important methods and properties are covered, although references to techniques omitted and fundamental factors are included to aid the acquisition of a deeper understanding, where this is required, and to appreciate the applications of thin films in those areas not covered elsewhere in this volume.

29.1 Deposition Methods

The deposition methods described in this section are those most commonly used. The physical methods of vacuum evaporation and sputtering are perhaps the most controllable, giving the best-quality films. In particular, molecular-beam epitaxy (MBE) is capable of providing very high-quality films. Examples of chemical methods, which are somewhat less flexible and limited to particular types of films, are also given. Perhaps the most important of these is CVD, but as will be seen the particular route chosen depends on the chemical properties of the material to be deposited.

29.1.1 Physical Deposition Methods

These could perhaps be described as physical vapour deposition (PVD) methods, since they involve direct deposition from the vapour phase, normally under reduced pressure. There are two main classes which are considered. The first of these is vacuum evaporation, which takes place at a low background pressure, i. e. high vacuum (HV) of the order of 10^{-4} Pa, although MBE systems normally operate at pressures significantly below this level. Secondly we have sputtering, which relies on the ejection of atoms or molecules from the surface

of a material target by a mechanism of momentum transfer involving an impact from (usually) ionised inert gas atoms such as argon; in order for this to occur a sufficient inert gas pressure is required to sustain a discharge, and thus the typical operating pressure is of the order of 1 Pa. Thus evaporated films are liable to have a higher intrinsic purity than sputtered films, which are prone to the incorporation of sputtering gas atoms. However, as these are generally inert there is often no deleterious effect on the film properties.

Vacuum Evaporation

During evaporation the evaporant is heated in vacuum by, for example, employing a high current through a refractory boat in which the evaporant is placed, or by using a high-current electron beam focussed on the evaporant. The purpose of this heating is to convert the condensed phase of the evaporant into the vapour phase, which then condenses elsewhere in the system in the form of a thin film. At a given absolute temperature T , there will in general be some of the evaporant in a condensed phase and some in the vapour phase. In thermodynamic equilibrium the Clausius–Clapeyron equation, relating the equilibrium vapour pressure p^* to the temperature T may be applied:

$$\frac{dp^*}{dT} = \frac{L}{T(\nu_g - \nu_c)}, \quad (29.1)$$

where L is the latent heat of vaporisation, representing the amount of energy required to convert a quantity of the condensed phase (liquid or solid) into the vapour phase at the given temperature. If L is expressed in J/mol, then ν_g and ν_c represent the molar volumes of the gaseous and condensed phases respectively. Although evaporation is not an equilibrium process, the importance of the equilibrium vapour pressure to evaporation is that maximum evaporation rates are dependent on the vapour pressure. Expressions for p^* may be obtained from (29.1) provided the temperature dependence of L is known. For the simplest assumption, where L is independent of T , we assume that the vapour obeys the ideal gas law. For one mole of the vapour

$$p^* \nu_g = RT, \quad (29.2)$$

where R is the universal gas constant. Further assuming that the volume of the vapour phase is very much greater than that of the condensed phase ($\nu_g \gg \nu_c$), combining the above two equations and integrating, an expression for p^* is obtained. This can be expressed in logarithmic form as

$$\log_{10} p^* = AT^{-1} + B, \quad (29.3)$$

where $A = -(L/R) \log_{10} e$ and B is a constant of integration. The constants A and B are tabulated by *Dushman and Lafferty* [29.21] for various metals using non-SI units, although in a slightly different form from the definitions of (29.3). In many cases such an expression for determining equilibrium vapour pressure is inadequate. The main reason for this is that the assumption of a constant latent heat L is invalid, particularly over a wide temperature range. When temperature variations in L are taken into account, (29.3) is modified by the addition of several additional terms, which may be determined from standard thermodynamic enthalpy and entropy data [29.22]. Tabulated values of coefficients for a logarithmic $p^* - T$ expression involving four coefficients are given by *Kubaschewski et al.* [29.23] for various elements and compounds over defined temperature ranges in both the liquid and solid phases. Even more helpful are direct tabulated and graphical data of the $p^* - T$ relationship in the case of various solid and liquid elements [29.20, 22, 24]. Examples of the $p^* - T$ dependence are given in Fig. 29.1 for several elements using the data of *Honig and Kramer* [29.20]. From this figure it is clear that p^* increases very rapidly with temperature, and that most metals require temperatures of up to about 1500 K to attain significant vapour pressures; however, the refractory metals (Pt, Ta, W, etc.) require far higher temperatures for evaporation and thus they are not normally deposited by this method, although they are very useful materials for evaporation boat ma-

Fig. 29.1 Experimental dependence of the equilibrium vapour pressure p^* on absolute temperature T for several elements, derived from the compilation of *Honig and Kramer* [29.20]. The point (•) on each curve indicates the melting point, except for that of carbon, which sublimes

terials, which require very low vapour pressures and high melting points.

It is a well-known result from the kinetic theory of gases, that the molecules of a gas at a pressure p impinge on surfaces at a rate

$$N_i = \frac{p}{(2\pi mk_B T)^{1/2}} \quad (29.4)$$

where N_i ($\text{m}^{-2}\text{s}^{-1}$) is termed the impingement rate, m is the mass of a gas molecule, k is Boltzmann's constant and T is the absolute temperature. In principle this equation applies equally well to residual gas molecules (N_2 and O_2) in an evaporation chamber, as well as to evaporant molecules in the vapour phase. It was noted previously that the equilibrium vapour pressure of a material largely determines the maximum evaporation rate. Hertz [29.25] observed for the case of mercury that evaporation rates were proportional to the difference between the equilibrium vapour pressure p^* and the reverse hydrostatic pressure p_h exerted at the surface of the evaporant. The *maximum* evaporation rate occurs when $p_h = 0$, and is equal to the impingement rate a vapour of the evaporant would exert at its equilibrium vapour pressure. This is given by an expression similar to (29.4), with pressure p^* , evaporation temperature T_e and mass of evaporant molecule m_e . This rate is rarely achieved, not only due to the hydrostatic pressure p_h , but also to a molecular reflection phenomenon proposed by Knudsen [29.26], which takes place at the evaporant surface. It was proposed that only a certain fraction α_v (the evaporation coefficient) of molecules make the transition from the condensed to the vapour phase. The net molecular evaporation rate, N_e , is then given by the Hertz-Knudsen equation

$$N_e = \frac{\alpha_v (p^* - p_h)}{(2\pi m_e k_B T_e)^{1/2}} \quad (29.5)$$

Under equilibrium conditions $p_h = p^*$ and there is no net evaporation; however, under nonequilibrium conditions, especially when $p_h \ll p^*$, the evaporation rate can be considerable. Values of the coefficient α_v have been tabulated in the literature for a selection of different elements and compounds [29.27].

Equipped with vapour pressure and evaporation coefficient data, it is straightforward to estimate the evaporation rate using (29.5). The molecular deposition rate N_R represents the number of evaporated molecules deposited on the substrate per unit area per second. It is clearly proportional to the evaporation rate N_e , depending on the geometry of the evaporation/deposition system. N_R is simply related to the thickness deposition

rate R (m/s) by

$$N_R = \frac{\rho R}{m_e} \quad (29.6)$$

where ρ is the density of the depositing film. An indication of the film quality is given by the impingement ratio K , representing the ratio of the rate at which ambient gas molecules impinge on the substrate to the rate of evaporated molecules depositing on the substrate. Hence

$$K = \frac{N_i}{N_R} \quad (29.7)$$

From (29.4) and (29.6) it is clear that $K \propto p/R$ for a given material. In order to reduce contamination by gas incorporation into the film, it is therefore necessary to operate at a low background gas pressure with a relatively high deposition rate. A simple calculation for copper shows that for $R = 1 \text{ nm/s}$, $N_R \approx 8.5 \times 10^{19} \text{ m}^{-2} \text{ s}^{-1}$. If we require $K < 10^{-3}$ for impinging oxygen molecules then the maximum value of N_i allowed is $8.5 \times 10^{16} \text{ m}^{-2} \text{ s}^{-1}$, which from (29.4) corresponds at room temperature to a pressure of about $3 \times 10^{-6} \text{ Pa}$. Such a pressure is in the range of ultra-high vacuum (UHV), and is not attainable in normal vacuum deposition systems. Increasing the deposition rate is the normal method of lowering K without moving into UHV, as is used in MBE. This may in principle be achieved either by increasing the evaporation rate by increasing T_e to raise p^* , or by increasing the proportionality constant between N_e and N_R by shortening the distance between the evaporant and the substrate. A useful table of values of K for various combinations of chamber pressure and deposition rate is given by Eckertová [29.1].

There is in principle a second limitation on the level of the background pressure in a vacuum system which is also derived from kinetic theory. By using a Maxwell-Boltzmann distribution function for the molecular velocities in a gas, it can be shown that the mean free path between collisions in the gas λ is given by [29.22]

$$\lambda = \frac{k_B T}{p\pi\delta^2\sqrt{2}} \quad (29.8)$$

where δ is the effective molecular diameter of a gas molecule. Values of δ are tabulated in the literature [29.21], and range from about 0.22 nm (He) to 0.49 nm (Xe). From (29.8) λ is inversely proportional to the pressure p , and this general relationship is shown for He, O_2 and Xe in Fig. 29.2. Since the values of δ do not vary greatly for different gases, the λ values for all common gases fall

Fig. 29.2 The dependence of mean free path λ on pressure p for helium, oxygen and xenon at 300 K. Mean free paths are calculated from (29.8) using values of molecular diameter δ from Dushman and Lafferty [29.21]

within a narrow range, as illustrated in the figure. The proportion of molecules $F(x)$ which have not suffered an intermolecular collision as a function of distance x since their last collision is given by

$$F(x) = \exp(-x/\lambda). \quad (29.9)$$

From this expression it is evident that for a deposition chamber size of about $\lambda/10$, less than 10% of molecules suffer a collision before hitting the walls of the chamber or the substrate, e.g. in a large vacuum chamber of dimensions about 1 m where the mean free path is about 10 m. From Fig. 29.2 a pressure of 10^{-4} Pa is sufficiently low to ensure that $\lambda > 10$ m. In evaporation processes we require that the evaporant molecules are not significantly dispersed by collisions with gas molecules en route to the substrate, and since the mean free path is relatively insensitive to the molecular diameter, λ is a suitable criterion to determine this. Thus smaller deposition chambers will not require as low a residual gas pressure as larger ones.

The geometry of the evaporation source and its positioning with respect to the substrate is an important consideration in determining the uniformity of a thin-film deposit. Expressions for the film thickness variation over the substrate for various types of source have been derived by Holland and Steckelmacher [29.28]. Traditionally the *point source* and the *small surface source* are used. It is assumed that the evaporation source, of either type, is located a distance h below the centre of a flat substrate, as shown in the inset to Fig. 29.3. It is obvious that the film thickness deposited directly above

the source at the point O will be thicker than elsewhere, since this is the closest point of the source to the substrate. For the case of the point source, molecules are emitted uniformly in all directions, and the ratio of the film thickness d deposited at the point P a distance l from O to the thickness d_0 deposited at O is given by

$$\frac{d}{d_0} = \frac{1}{[1 + (l/h)^2]^{3/2}}. \quad (29.10)$$

For a small surface source, the emission follows a cosine law, and the thickness distribution is given by

$$\frac{d}{d_0} = \frac{1}{[1 + (l/h)^2]^2}. \quad (29.11)$$

Plots of these two functions are shown on Fig. 29.3 for the point source P and the small surface source S. For both sources, there is a rapid diminution in the thickness ratio d/d_0 , which falls off to 0.985 and 0.98 respectively for the point and surface sources at a value of $l/h = 0.1$. When the substrate is relatively small, the thickness uniformity is thus better than 2%. Uniformity can be enhanced, for these two small sources, by increasing the source–substrate distance h , but at the expense of consuming more evaporant material. It has also been shown that a substantially uniform deposit will be obtained for a point source if the source is placed at the centre of

Fig. 29.3 Film thickness profiles calculated for evaporation from various sources onto a flat parallel substrate. Thickness ratio d/d_0 is given as a function of the ratio l/h , as shown in the inset. Sources include the small surface source (S), the point source (P) and a thin ring source (R) of radius b , where $b/h = 0.75$. Profiles are calculated, respectively, from (29.11), (29.10) and from an expression given by Glang [29.22]

a sphere and the substrates placed on the surface. For a surface source a uniform thickness distribution is obtained if both the source and the substrates are placed on the surface of a sphere [29.28].

Other systems for obtaining uniform thickness are based on the use of either extended sources, or substrates rotating around a central axis with respect to an off-centre source, such that variations in the thickness average out. *Holland* and *Steckelmacher* [29.28] have addressed ring sources in addition to strip and cylindrical sources evaporating onto a plane-parallel substrate. The ring source has also been treated by *von Hippel* [29.29] and the small surface source evaporating onto a rotating plane parallel substrate has been discussed by *Macleod* [29.30]. Expressions for ring and large surface sources are given by *Glang* [29.22]. A ring source can be considered to be a narrow ring of radius b , which is usually placed parallel to a flat substrate. This introduces an additional controllable variable which influences the thickness distribution. Thickness distributions may be obtained by calculating the distribution arising from an element of the ring source and then summing over all elements in the ring. For small b/h the thickness distribution reduces to that of the small surface source. For b/h larger than about unity the uniformity is also poor as the maximum in the distribution moves away from the central axis towards the source radius. However, for intermediate ranges, in particular b/h of about 0.7–0.8 there is considerable uniformity in thickness up to l/h of about 0.6. This is also illustrated in Fig. 29.3, where the curve R shows the thickness distribution for a narrow ring source with $b/h = 0.75$, calculated from the formula given by *Glang* [29.22]. Extended disc source thickness distributions may be obtained by integrating the thickness distribution derived for a narrow ring source from radius zero to radius b , but in general the thickness uniformity is not as good as for ring sources. Expressions for ring source of finite width can be determined by subtracting the disc source distribution for the inner radius from that of the outer radius. Diagrams illustrating the thickness distributions for several sets of ring and disc sources are given by *Glang* [29.22]. *Behrndt* [29.7] gives further details and references for such sources, and a discussion of the results of using combinations of several rod-like sources. Further attempts to minimise thickness variations have resulted in the evolution of various *planetary* deposition systems, so called because the rotating substrate plane is itself rotated around a vertical axis. A typical example of such a system and its performance is given in the literature [29.31].

Before describing the practical details of the evaporation process, it should be mentioned that, whatever type of evaporation process is used, some consideration needs to be given to the substrate. There are three basic types of substrate commonly used: glasses, single crystals and polycrystalline ceramics. Ceramics are particularly useful for high-temperature deposition processes. Although the substrate material may be predetermined (e.g. silicon wafers for microelectronics, optical glass for coatings on lenses, etc.), there are frequently factors which can be selected to increase the probability of obtaining good-quality films. The substrate planarity is important, in order to reduce the effect of defects. Electrical resistivity should in general be high in order to minimise surface leakage currents. Thermal properties include a consideration of the coefficient of expansion, which should be comparable to that of the deposited film to reduce the probability of thermally induced stresses in the films. Thermal conductivity should be high for films whose applications will entail significant power dissipation. A full description of thin-film substrates and the associated problems of substrate cleaning are discussed in detail by *Brown* [29.32].

Resistive evaporation is the most commonly used evaporation technique, although it is unfortunately not suitable for certain applications. It entails the resistive heating of an evaporation source, by passing a high current either through the source itself or through an adjacent heater. There are a large number of practical evaporation sources for various applications which are described in the literature [29.1, 22, 28]. The main requirement for any evaporation source is that the source itself will not emit its own vapour at the operating temperature. If metallic sources are used, the equilibrium vapour pressure of the metal must be negligible in comparison to that of the evaporant. A glance at Fig. 29.1 shows that the refractory metals (such as Pt, Ta and W) have equilibrium vapour pressures very low compared to about 1 Pa at temperatures up to about 2000 K, and are therefore suitable for evaporation of many materials. Carbon and oxides of aluminium or magnesium may also be used in evaporation, although owing to their low electrical conductivity refractory metal heaters are often used in conjunction with these. However, at elevated temperatures the oxides themselves may dissociate, with the liberated oxygen reacting with the evaporant to form its own oxide. For this reason the refractory metals cannot themselves be evaporated from oxide crucibles. Furthermore carbon may react with metals to form carbides well below 2000 K. Having chosen a suitable evaporation source, the vacuum deposition

chamber is pumped down to the required background pressure and deposition may commence. The temperature of the source is increased such that the vapour pressure increases to a value consistent with a reasonable evaporation and hence deposition rate. The substrate is normally shielded using a metallic shutter until the required deposition rate is established, when the shutter is removed. The deposition rate is usually monitored by one of several methods [29.7, 22]. The quartz crystal method entails depositing the evaporant material on a vibrating quartz crystal, whose frequency varies linearly with the thickness of material deposited [29.33, 34]; the deposition rate is obtained by electronically differentiating the thickness signal with respect to time. Optical thickness monitoring methods are also used, particularly in applications where films are required for optical purposes, and require films having an optical thickness of multiples of $\lambda/4$, where λ is the wavelength for which the optical film is designed [29.7, 22]. These thickness multiples correspond to maxima and minima in reflected light intensity, which can easily be monitored during deposition. When the required film thickness is attained, a shutter is again used to curtail further film deposition and the evaporation process is stopped. Sequences of several film layers may be deposited by using a suitable sequential masking system [29.35].

Apart from simple vacuum evaporation there are also several other types of evaporation, which entail using alternative methods to heat the evaporant, or cater for various problems encountered in the deposition of alloys and compounds. In electron-beam evaporation the evaporant material is placed in a ceramic hearth, which is bombarded by high-energy electrons. The main advantage of this method is that considerably higher temperatures of above 3000 K may be obtained than with resistive evaporation methods. This allows evaporation of the refractory metals and also elements such as boron and carbon (which sublimes). Other advantages are the evaporation of reactive metals such as Al, which are prone to contamination due to alloying, and situations where high purity is required.

For non-elemental (multicomponent) films there are several methods which may be employed. The main problem with such films is that, because of differences between the vapour pressures of the evaporant components, the Hertz–Knudsen expression of (29.5) predicts that the compound will evaporate noncongruently, i.e. with different evaporation rates for each element, and the deposited film will not in general replicate the composition of the evaporant. The problem is compounded

because the proportion of each component present will therefore vary throughout the evaporation process, and the overall composition of the deposited films will vary throughout its thickness. In the evaporation of alloys, each component establishes its own vapour pressure at a given temperature, which may be predicted by *Raoult's law* for an ideal solution. This states that the vapour pressure established by each individual component is proportional to the mole fraction of the component present. Under these circumstances it is relatively simple to adjust the proportions of the alloy components to achieve the required film composition. However, complications occur in nonideal solutions, where the interactions between different types of atoms vary and an empirical parameter known as the activity coefficient, a , is defined. Knowing this it is possible to determine the vapour pressure for the component and hence the evaporation and deposition rates. Activity coefficients for various important systems, such as nichrome (a Ni–Cr alloy), are given in the literature [29.36]. However, as noted previously the mole fractions present in the evaporant are time-dependent and the composition of the films will vary during deposition. A parameter K has been determined, which if maintained close to unity should result in congruent evaporation throughout the entire deposition process. Further details are given by *Zinsmeister* [29.37]. Additional comments on the evaporation of both nichrome and permalloy alloys are given by *Glang* [29.22].

On evaporation of compounds, a wealth of chemical reactions can occur, which leads to a variety of different evaporation mechanisms. Frequently more than one reaction may operate simultaneously. Four simple generic reactions have been listed by *Glang* [29.22], which include many of the materials which can be successfully evaporated. We consider only compounds AB composed of the elements A and B , and denote the phase of the material by s (solid), l (liquid) or g (gas). Some compounds (solids or liquids) do not dissociate on evaporation and the reaction can be expressed simply as

There is then only the single vapour phase $AB(g)$ produced. Other compounds dissociate on evaporation into two different vapour species. One reaction which is typical of the evaporation of chalcogenides and some simple oxides is given by

whereas the group IV dioxides tend to dissociate according to the reaction

In compounds of elements whose volatilities are significantly different, frequently one element enters the vapour phase while the other remains in the solid (or possibly liquid) phase. The compound decomposes into its different elements, with the simplest reaction of this type being

Examples of materials evaporating without dissociation following (29.12) are the simple oxides GeO, SiO, SnO, the fluorides CaF₂ and MgF₂, and PbS. In general the evaporation of these materials can therefore be considered as analogous to those of the elements, and where available simple p^*-T data give the vapour pressure. Materials which follow (29.13) are primarily the II–VI chalcogenides, in particular the cadmium compounds CdS, CdSe and CdTe, and several simple oxides such as BaO, BeO, CaO, MgO, NiO and SrO. A full review of the electrical and structural properties of the cadmium chalcogenides is given by *Gould* [29.38]. Equation (29.14) is followed by many of the group IV dioxides, such as SiO₂, SnO₂, TiO₂ and ZrO₂, which dissociate into their lower oxides and molecular oxygen. Decomposition, as described by (29.15) is followed by most of the metallic borides, carbides and nitrides [29.22]. Other modes of decomposition, such as those for the technologically important III–V compounds, are also described in this reference.

Provided the relevant reaction for the evaporation process is known [e.g. as given by Eqs. (29.12–29.15)] it is possible to determine the equilibrium vapour pressure using standard thermodynamic tables. The law of mass action may be used to determine the equilibrium state of the chemical reaction, and for evaporation, the pressures of the various phases present contribute to a temperature-dependent equilibrium constant K_p , which is given by

$$K_p = \prod_i (P_i)^{v_i} \quad (29.16)$$

where P_i represents the vapour pressure for each of the various components of the vapour expressed in standard atmospheres and the v_i are the molecular coefficients. K_p is related to the thermodynamic parameter ΔG^0 , the standard change in Gibbs free energy per mole for the reaction, by the expression

$$\Delta G^0 = -RT \ln K_p, \quad (29.17)$$

where R is the universal gas constant. Free-energy data is tabulated for many materials in the literature [29.23, 39] and the use of (29.16) and (29.17) allows realistic estimates of the equilibrium vapour pressures to be determined and the evaporation rates estimated. Further discussions are given by *Glang* [29.22]. Nevertheless, although the theoretical framework is in place for the controlled evaporation of compounds, the exact type of dissociation and decomposition are not known in all cases, and for compounds consisting of three or more elements this problem is compounded. Some materials are therefore not amenable to direct evaporation from a single source.

For these cases various special evaporation techniques have been developed, all of which aim to replicate the composition of the evaporant in the deposited film, by ensuring that the different molecules arrive at the substrate in the desired proportions and at a constant rate. Reactive evaporation is a process whereby one component of the desired film is evaporated resistively in the normal manner, while the other component is present in the evaporation chamber in the form of a gas. This method is most commonly used where oxide films are required and oxygen gas present in the chamber combines with a metal at the substrate to form the oxide. The impingement ratio K , given by (29.7) is optimised so that evaporant and gas molecules reach the substrate in a predetermined ratio. Oxides of the common metals have been deposited by this method, including those of Al, Cr, Cu and Fe; additionally tantalum and titanium oxides have been prepared for dielectric applications. Reactive evaporation has also been used for compounds other than oxides. For instance, stoichiometric CdS films have been obtained by the evaporation of CdS in a sulphur vapour [29.40]. The sulphur vapour has the effect of discouraging the appearance of nonstoichiometric Cd-rich films which occur when CdS is evaporated alone. Nitrides may also be deposited in some cases by the use of a nitrogen atmosphere. The utility of this technique has been demonstrated in the reactive evaporation of silicon oxide, SiO_x, by *Timson* and *Hogarth* [29.41]. The evaporant is a mixture of the monoxide, the dioxide and possibly also free silicon. A sequence of films, varying in composition between SiO and SiO₂ as determined by electron spin resonance studies were obtained, depending on the ratio of the deposition rate to the oxygen pressure R/p . A useful nomogram for use in reactive evaporation is given by *Glang* [29.22].

Co-evaporation, sometimes known as the three-temperature technique, involves the simultaneous evaporation of two or more materials from separate evap-

Fig. 29.4 Schematic diagram of a molecular-beam epitaxy (MBE) system for the deposition of III–V semiconductor compounds. After [29.42] with permission from Elsevier Science

oration sources. The essential feature of this process is that the rate of molecular arrival at the substrate may be controlled by individually controlling the temperatures of the evaporation sources. A major advantage of this method is that materials with widely different vapour pressures at a given temperature may be co-deposited by increasing the temperature of the less-volatile material. This method has found applications in the deposition of II–VI compounds such as CdS and CdSe, and also the III–V compounds such as AlSb, GaAs, InAs and InSb. It is also used for the deposition of alloy films.

Flash evaporation is another technique used for deposition of layers whose components have widely different vapour pressures. The evaporation is constrained so that only very small amounts of the compound completely vaporise almost instantaneously. The various components normally evaporate noncongruently, but because only very small quantities are evaporated rapidly, any inhomogeneity in the deposited films is limited to a few atomic layers. The process is repeated by evaporating further small quantities of evaporant. Several alternative arrangements have been developed to evaporate small particles, by continuously feeding powdered evaporant from a hopper into a heated evaporation source. The rate of delivery needs to be controlled such that at any given time there will be a number of evaporant particles in the source at various stages of the evaporation process. This ensures that the vapour emerging from the source contains contributions from many individ-

ual particles, resulting in an overall vapour composition which approximates to that of the evaporant powder. The method has been used particularly for III–V compound semiconductors such as GaAs.

Finally, the method of molecular-beam epitaxy (MBE) should be included here as a particularly sophisticated example of evaporation (or co-evaporation). In MBE the background pressure is considerably lower than in the case of the simpler evaporation techniques, i. e. well into the UHV range. This effectively eliminates the effects of background gas impingement, drastically improving the purity of the films. Several sources (effusion ovens) may be used simultaneously, each of which is separately controlled. These permit the deposition of compounds and precisely controlled doping of semiconductors. Sophisticated monitoring and isolation techniques are employed, and deposition sequences are usually under computer control. MBE is used particularly for the preparation of III–V compounds [29.42, 43] and silicon [29.44]. Figure 29.4 illustrates a typical MBE system for use in the deposition of III–V compounds [29.42]. A full description of MBE, together with other epitaxial growth techniques is given elsewhere in this volume in Chapt. 14.

Sputtering

The technique of sputtering in its various forms is of secondary importance only to evaporation for the deposition of thin films, offering certain advantages for the de-

position of high-melting-point and dielectric materials. Sputtering is essentially the removal of particles from the surface of a *target* of the deposition material, by the action of incident energetic particles (normally positive ions). It is generally considered that the sputtering mechanism is the result of the transfer of momentum from the incident particles to the target atoms, some of which become dislodged. Energy acquired by other atoms interacting with the dislodged atoms can be sufficient to overcome the surface binding energy potential barrier. The net effect of a large number of atomic interactions is for a certain proportion of the target to be released (or sputtered) from the surface. Sputtered atoms typically have energies much higher than their evaporated counterparts. For low-energy sputtering with incident energy 1 keV, an ejected particle may have an energy of 10 eV, since typically 1% of the incident energy is transferred to each sputtered atom. In contrast, the thermal (kT) energy of an atom evaporated from a source at 2000 K is less than 0.2 eV. Such considerations have implications regarding the sticking coefficients for deposited materials (i.e. the probability that an atom reaching the substrate condenses on it), which is generally higher for higher-energy atoms.

Sputtering is limited by a threshold energy, below which it will not occur for a given ion/target combination. Threshold energies for a wide range of incident ions and target materials are of the order of 20–30 eV; experimental values for some common ion/target combinations are given by *Wehner and Anderson* [29.45]. These workers have pointed out that the threshold energy appears to be approximately four times the latent heat of sublimation per atom, equivalent to the surface binding energy. However, for practical sputtering considerations, incident energies are normally at least a few hundred electronvolts, well above the threshold energy. The efficiency of sputtering, measured by the sputtering yield, is also very low at low incident ion energies.

The sputtering yield is the most important sputtering parameter, and its variation with the target material and the incident ion energies is of major concern in both theories of sputtering and in practical sputtering deposition techniques. Sputtering yield $S(E)$ is defined as the ratio of the number of sputtered atoms to the number of incident ions. Hence

$$S(E) = \frac{N_s}{N_{\text{ion}}} , \quad (29.18)$$

where N_{ion} is the impingement rate of incident ions and N_s is the sputtering rate of the target. Its primary

variation is with the incident ion energy E . However, it also depends on the atomic properties of the incident ions and the target atoms. In the following discussion Z_1 and m_1 refer to the atomic number and mass of the incident ions, and Z_2 and m_2 refer to the corresponding quantities for the target material. The dependence of sputtering yield on the atomic number of the incident ions is quite striking, as shown in Fig. 29.5 [29.46]. This shows the variations of $S(E)$ for 45-keV incident ions onto targets of silver, copper and tantalum. Maxima in $S(E)$ occur corresponding to the noble gases Ne, Ar, Kr, and Xe. This dependence is one reason why the noble gases are most commonly used as the incident ion species, the second being that their inclusion into deposited films is unlikely to cause significant problems, due to their chemically inactive nature.

A number of theories have been developed to predict the dependence of sputtering yield $S(E)$ on the incident beam energy E . *Keywell* [29.47] assumed that the incident ions interacted with the sputtering target as if they were hard spheres, with the incident ion energy decreasing exponentially with the number of collisions. A discussion of this and other early models is given in the literature [29.45, 48]. More recent models [29.49, 50] have taken account of the scattering of incident ions by the atomic nucleus, and screening effects due to the electron cloud are also included, based on the Thomas–Fermi potential. This predicts a characteristic screening length a , which depends on the atomic numbers of the incident and target atoms, Z_1 and Z_2 , respectively. The screening length is given by

$$a = \frac{a_0}{(Z_1^{2/3} + Z_2^{2/3})^{1/2}} , \quad (29.19)$$

where $a_0 = 5.29 \times 10^{-11}$ m is the Bohr radius of the ground state of the hydrogen atom. Another parameter which is often invoked in sputtering models is the energy transfer coefficient, γ . For an incident ion of mass m_1 and energy E , impacting on a stationary target atom of mass m_2 , the maximum energy E_{max} the target atom will attain is given by

$$E_{\text{max}} = \gamma E , \quad (29.20)$$

where

$$\gamma = \frac{4m_1m_2}{(m_1 + m_2)^2} . \quad (29.21)$$

In most collisions the incident ion will lose some energy to the target lattice, resulting in the acquisition of an energy less than E_{max} by the target atom. γ has a maximum value of unity for $m_1 = m_2$, but

Fig. 29.5 Sputtering ratios of silver, copper and tantalum targets for different ions of energy 45 keV. After [29.46] with permission from Elsevier Science

this is neither a sufficient nor a practical condition for obtaining high sputtering yields owing to the impracticability of having identical sputtering ions and target material as well as the striking periodic dependence of $S(E)$ on Z_1 noted earlier. Two well-known sputtering models are now outlined, both of which have been reasonably successful in predicting sputtering yields.

In the model of *Pease* [29.49], which is also outlined elsewhere in the literature [29.51], ions are considered to interact with the target atoms near to the surface, which if displaced from their lattice sites are termed *primary knock-ons*. The mean energy of primary knock-ons before further interactions is denoted by \bar{E} . The threshold energy for displacement of a target atom, either by an incident ion or by a primary knock-on is denoted by E_d . Collisions with stationary atoms result in slowing down of displaced atoms, and in some cases a reversal of momentum and escape from the target surface, providing they still retain energy greater than E_s , the surface binding energy per atom. The number of atomic layers which contribute to the sputtering process is established by considering the average number of collisions n that a primary knock-on of energy \bar{E} will make before its kinetic energy is reduced to less than that re-

quired to leave the target surface, i.e. E_s . This is given by $2^n = \bar{E}/E_s$ or

$$n = \frac{\ln(\bar{E}/E_s)}{\ln 2}. \quad (29.22)$$

While engaged in n collisions the primary knock-ons diffuse on average $n^{1/2}$ atomic layers toward the surface, and thus $(1 + n^{1/2})$ layers are involved in sputtering of material liberated by primary knock-ons only. The total number of atomic layers involved in sputtering is also equal to this expression. We also have to consider the probability of interaction in a given atomic layer, and denote the number of atoms per unit volume in the target by N . If these atoms are considered to be arranged in uniform crystallographic layers in three dimensions, the atoms in each layer will have an area density of $N^{2/3}$. If σ_p denotes the cross section for interaction between incident ions and target atoms, the probability of interaction in a given atomic layer is given by the product of the number of atoms per unit area and their interaction cross sections, or $\sigma_p N^{2/3}$. The total probability of producing a primary knock-on which can contribute to the sputtering process is then given by the product of the probability of interaction in a given atomic layer and the number of layers involved in sputtering, i.e.

$\sigma_p N^{2/3} (1 + n^{1/2})$. An estimate of the number of atoms displaced per primary knock-on is $\bar{E}/2E_d$ [29.52] of which half, or $\bar{E}/4E_d$, will be directed towards the surface. The total sputtering yield $S(E)$ is then given by the product of the probability of producing primary knock-ons and the number of displaced atoms produced by each. Hence

$$S(E) = \sigma_p \bar{E} N^{2/3} \frac{1}{4E_d} \left[1 + \left(\frac{\ln(E/E_s)}{\ln 2} \right)^{2/3} \right] \quad (29.23)$$

where the expression for n in (29.22) has been substituted.

In (29.23) for the sputtering yield, N , E_d and E_s are constants depending on the target material and E_d is normally determined from radiation damage experiments. However, σ_p and \bar{E} are energy-dependent variables, which depend on the atomic numbers Z_1 and Z_2 , the Thomas–Fermi screening length a , and the maximum target-atom energy E_{\max} . It is not appropriate to give these expressions here, but it is worth mentioning that different expressions are applicable in different incident ion energy ranges, defined by $E < L_A$, $L_A < E < L_B$, and $L_B < E$. Further details concerning the threshold energies L_A and L_B are given in [29.49, 51]. Calculations of sputtering yield predicted by this model are reasonably consistent with experiment, showing a sharp increase above a certain threshold energy which is determined by E_s , a broad maximum and a relatively slow decrease at higher energies [29.49].

The model of *Sigmund* [29.50] represents a comprehensive theory of sputtering, particularly for single-element solids, although this has led to a certain degree of complexity in its general form. The model has been revised and extended [29.48] and tested against a considerable amount of data produced by many different workers [29.53]. The emphasis in this section is to briefly outline the model, to provide a basis for the calculation of $S(E)$ at normal incidence for low- and high-energy sputtering, and to give useful references to the required data. Various approximations made and some of the conditions of validity are omitted. Being a multiple-collision process, sputtering may be treated by using the formalism of transport theory, and in the Sigmund model the Boltzmann transport equation is solved. The sputtering yield at normal incidence is given by

$$S(E) = A \alpha N S_n(E), \quad (29.24)$$

where A is termed the material factor, and depends only on the target material. α is a dimensionless factor, effectively depending only on the ratio of the target atom

to incident ion masses m_2/m_1 . The factor α is given for various different conditions in the literature [29.48, 50]. As in the model of *Pease* [29.49], N represents the number of atoms per unit volume in the target. $S_n(E)$ is the nuclear scattering cross section, depending on the interaction probability between the incident ions and the target atoms at a given energy.

The material factor A arises in the sputtering yield expression as a result of integrating the number of sputtered atoms emitted in all directions with all possible energies. According to Sigmund, the material factor

$$A = \frac{3}{4\pi^2} \frac{1}{NC_0 E_s}, \quad (29.25)$$

where $C_0 = \frac{1}{2}\pi\lambda_0 a_{\text{BM}}^2$, λ_0 is a constant approximately equal to 24, and $a_{\text{BM}} = 2.19 \times 10^{-11}$ m is the Born–Mayer potential characteristic screening radius. E_s represents the surface barrier energy, as in the model of Pease. Making these substitutions into (29.24) gives a more useful formula for the sputtering yield [29.45] as

$$S(E) = \frac{1}{16} \frac{\alpha S_n(E)}{\pi^3 a_{\text{BM}}^2 E_s} \quad (29.26)$$

which applies both for low- and high-energy sputtering. An expression for E^* , the boundary between low-energy and high-energy sputtering, is given in the literature [29.50], and is typically a few hundred electronvolts, depending on the atomic masses and atomic numbers of the incident ions and the target atoms. For low-energy sputtering ($E < E^*$) the nuclear scattering cross section can be approximated by

$$S_n(E) = C_0 E_{\max} = \frac{1}{2}\pi\lambda_0 a_{\text{BM}}^2 E_{\max}, \quad (29.27)$$

where $E_{\max} = \gamma E$ from (29.20). Substituting into (29.26) yields

$$S(E) = \frac{3}{4} \frac{\alpha \gamma E}{\pi^2 E_s}. \quad (29.28)$$

Hence for low-energy sputtering $S(E)$ is directly proportional to the sputtering energy, where α and γ effectively depend only on the ratio m_2/m_1 and E_s is a constant for the target material.

For higher incident ion energies ($E > E^*$) the Thomas–Fermi, rather than the Born–Mayer interaction potential is applicable, and a simple approximation for $S_n(E)$ is not available. It is therefore necessary to determine its value from tables or graphical data, calculating $S(E)$ directly from (29.26). Incident ion energies E and nuclear scattering cross sections $S_n(E)$ may be expressed in terms of reduced or Thomas–Fermi variables ε and $s_n(\varepsilon)$ [29.48, 50]. $s_n(\varepsilon)$ is a universal function

of ε , depending on the details of the screened Coulomb function used [29.48]. The detailed dependence of $s_n(\varepsilon)$ on ε utilised in the Sigmund model is that given by Lindhard et al. [29.54]. For ease of computation E_{TF} , the Thomas–Fermi energy unit has been calculated for various incident ion/target combinations [29.48]. E_{TF} represents the ratio E/ε , and thus ε and hence $s_n(\varepsilon)$ may be obtained. $S_n(E)$ may then be determined from the reduced value.

Agreement between predicted and measured sputtering yields as a function of incident ion energy are good. Andersen and Bay [29.53] have reviewed sputtering yield measurements at normal incidence for a considerable number of incident ion and target species, and generally concluded that sputtering yields for high-yield materials (e.g. Ag, Au, Cu, Zn) are predicted well by the theory, while for low-yield materials (e.g. Nb, Ta, Ti, W) it was over-estimated by a factor of up to three. A fuller discussion, to which the reader is referred, shows that the model breaks down for certain combinations of Z_1 , Z_2 and E due to the existence of inelastic collisions, non-isotropic and nonlinear effects (spikes) in the collision cascade and unallowed-for surface effects. The regions of validity of the model are neatly presented in terms of a three-dimensional (Z_1 , Z_2 , E) space, and illustrate the fact that (29.26) is an amazingly good prediction for a large number of (Z_1 , Z_2 , E) combinations of practical interest.

Sputtering yields may be determined experimentally by measuring the decrease in mass of a sputtering target. Normally such experiments are performed using ion-beam sputtering, in a fairly high-vacuum environment. The target area bombarded by the beam is small, and fairly low sputtering rates are achieved, but it has the advantage that ion energies are accurately given by the accelerating potential. The methods of sputtering normally used for the preparation of thin films are based on the establishment of a population of positive ions in a low-pressure gaseous environment. Such techniques depend on the establishment of a glow discharge, and require a considerably higher operating pressure, whereas ion-beam sputtering does not require the presence of gas molecules in the deposition chamber, and can therefore be used under UHV conditions, where gaseous contamination effects are minimised. A complicating factor, which often has to be taken into account, is that some incident ions may become embedded in the target, thus tending to increase its mass. The net loss of material from the target Δm is then the difference between the mass of material sputtered and the mass gain of the target. If N_{ion} and N_s are the incident ion impinge-

ment rate and the atomic sputtering rate of the target respectively (29.18), and m_1 and m_2 are the incident ion and target atom masses, it is simple to calculate the mass loss and increase of a given target with bombarded area A sputtered for a time t . The loss of mass is given by $N_s m_2 A t$, and the increase in mass is given by $N_{ion} \Gamma m_1 A t$, where Γ is the probability that an incident ion becomes embedded in the target. Hence

$$\Delta m = N_s m_2 A t - N_{ion} \Gamma m_1 A t \quad (29.29)$$

or

$$S(E) = \frac{N_s}{N_{ion}} = \frac{\Delta m}{m_2 N_{ion} A t} + \Gamma \frac{m_1}{m_2}. \quad (29.30)$$

Frequently the second term on the right-hand side of this equation is negligible, and the sputtering yield is then given by the first term only. This is particularly applicable for large ion doses, while for intermediate doses a detailed empirical knowledge of the value of Γ is required. For low ion doses the approximation $\Gamma = 1 - R_0$, where R_0 is an ion reflection coefficient, may be used [29.53]. It is often useful to express the sputtering yield in terms of the ion current at the cathode $I_c = e N_{ion} A$, where e is the electronic charge and the sputtering yield is then given by [29.1]

$$S(E) \approx \frac{e \Delta m}{m_2 I_c t}. \quad (29.31)$$

Measurements of the ion current, target mass loss and the sputtering time are then all that are necessary to calculate $S(E)$. Although strictly speaking the above expressions are only applicable for sputtering performed with ions of a single energy, they may also be applied to a first approximation for practical sputtering methods using the glow discharge.

Although ion-beam sputtering is a very useful technique for measuring sputtering yields and comparing with theoretical predictions, it is not normally used for routine film deposition, owing to the need for UHV conditions, the low sputtering rate obtained and the associated expense. Virtually all sputtering methods used for the deposition of thin films utilise the glow discharge phenomenon. When a gas at reduced pressure is subjected to an applied voltage, usually in the range of a few hundred to several kilovolts, any free electrons will be accelerated in the field, acquiring energy and ionising the gas molecules to produce a plasma. Under the influence of the field the positively ionised gas molecules are accelerated towards the cathode and free electrons towards the anode. The gas pressure required for the establishment of such a discharge is of the order

of a few pascals, which in turn is determined by the molecular concentration required to maintain the mean free path within suitable limits to initiate and sustain the discharge. The basic principles of the glow discharge are well known and documented [29.55, 56] and need not concern us here. However, it should be noted that the positive ions tend to accumulate in front of the cathode (the cathode-fall region), across which most of the applied voltage is dropped. Thus the electric field between the cathode and the anode is distinctly nonlinear, and most of the energy acquired by the ions in their journey to the cathode is obtained in the cathode-fall region.

It is relatively simple to set up a self-sustained glow discharge, although the behaviour of the discharge depends in a fairly complex manner on the pressure, the applied voltage and the geometry of the system. Inert gases such as argon are generally used, unless the sputtered film relies on a reaction between the sputtering gas and the sputtered material to produce the required compound film. Once the discharge is established, the cathode is continuously bombarded by energetic ions, and provided the energy of these ions is sufficient, sputtering of the cathode will occur. Thus if the target is sufficiently conductive, all that is necessary is to make the cathode of the target material. Substrates on which deposition will occur are normally placed parallel to the target at the anode so that the sputtered atoms need only cover a short distance before deposition. The energy of the sputtered atoms when they reach the substrate is considerably higher than in the case of evaporation, leading to better adhesion. Furthermore, sputtered compounds are normally deposited without dissociation, and therefore the stoichiometry of the target material is usually preserved in the deposited film. This basic form of sputtering is normally termed *diode sputtering*, since only two electrical connections are required.

Basic diode sputtering operates reasonably satisfactorily, but has a major disadvantage in that the sputtering rate N_s depends directly on the impingement rate of the incident ions N_{ion} and thus also on the discharge current. At low gas pressures the supply of ions is limited and thus the discharge current and the sputtering rate are low. Moreover, at sufficiently low pressures the electrons do not ionise a sufficient number of gas atoms to sustain the glow discharge. This low-pressure limit is in fact a major drawback in diode sputtering, since enforced operation at higher pressures above about 3 Pa results in significant film contamination. For this reason sputtering was for many years rejected in favour of evaporation for thin-film deposition. A major improvement in sputtering technology, which enabled sputtering

to be performed at lower pressures was the introduction of *triode sputtering*. In this technique, the discharge is maintained by using an additional source of electrons, so that it is not totally dependent on secondary electron emission from the cathode. Electrons are supplied by an additional thermionic emitter, consisting of a filament through which a current is passed. The electron concentration in the plasma can be readily controlled by varying the anode potential or the filament current, while the ion current is directly controlled by the target potential. A further innovation usually employed in triode sputtering systems is the use of a coil to set up a magnetic field, which forces electrons from the emitter to travel in spiral paths, thus greatly increasing the distance travelled from the emitter before they are collected by the anode. This enhances the ionisation probability α , and thus the supply of positive ions.

It should be emphasised that both diode and triode sputtering may not be used for the sputtering of insulators – a very important class of materials. Since positive ions are responsible for the sputtering process, these need to be neutralised by electrons from the external circuit. In the case of insulators a positive charge builds up at the surface of the target, and this charge cannot leak away through the insulator. Sputtering ceases when the positive charge causes the potential at the target surface to approach that of the plasma. Various methods, such as bombarding the target surface with electrons, have been attempted to solve this problem, but in general with little success. Glow discharge sputtering of insulators is generally therefore performed reactively, or with alternating radio-frequency (RF) fields, as described later.

As with evaporated films, there are a number of problems associated with the deposition of alloys and compounds. The best theories of sputtering yields are typically inaccurate by a factor of two or so. Empirical determinations are normally required for films of controlled composition to be deposited. Nevertheless, sputtering of multicomponent or compound targets is frequently all that is necessary to obtain films varying only marginally from the target composition. *Maisel* [29.57] suggests that during the initial sputtering run an *altered region* is formed on the surface of the target, which is deficient in the target component having the highest sputtering yield. Thus although stoichiometric films will not normally be deposited during the initial sputtering run, such films may generally be deposited during subsequent runs, since the deficiency in the higher sputtering rate material compensates for its greater removal rate [29.51, 57]. Minor differences between the compositions of the film and target do still

occur, but are normally the result of oxidation or of the evaporation of one component at high temperatures. When compounds are sputtered the incident ion energies are often sufficient to break the chemical bonds, again leading to a deficiency in one component. *Reactive sputtering* and *co-sputtering* are specifically designed to give greater flexibility during the deposition of multicomponent films.

Reactive sputtering involves the sputtering of a target using a sputtering gas which is amenable to chemical combination with the target material. The gas used may be either solely the reactive species, or a mixture of the reactive species and an inert sputtering gas, such as argon. Clearly the process is suitable for preparation of certain insulators which cannot be prepared by the previously mentioned sputtering techniques. Deposition rate depends primarily on the target sputtering yield, through the energy of the incident sputtering ions, the gas pressure and the distance between the target and the substrate. For example, *Pernay et al.* [29.58] have concluded that the deposition rate is primarily determined by a reduced electric field E^* , given by E/p , where E is the mean electric field between the cathode and the anode, and p is the gas pressure. When a copper target was sputtered in a mixture of oxygen and argon, either Cu_2O , CuO or Cu were deposited depending on the value of E^* and the oxygen concentration [29.59]. Reactive sputtering has been used mainly to deposit oxide films which have insulating or semiconducting properties. Among the common oxides that have been studied are those of aluminium, cadmium, copper, iron, silicon, tantalum, tin and titanium. Oxides of niobium, thorium, vanadium and zirconium have also been investigated, as have the rare-earth oxides of hafnium, lanthanum and yttrium. The other major non-oxide compounds which have been investigated are the nitrides, with silicon nitride, Si_3N_4 , receiving most attention due to its utility both as an insulator and in variants of the silicon planar process for integrated-circuit fabrication. This material has been prepared using a Si_3N_4 target and a mixture of argon and nitrogen as the sputtering gas [29.60]. Carbides and sulphides have also been sputtered reactively. In all cases it is imperative that the stoichiometry of the deposited films is determined using the normal chemical techniques, and the deposition parameters adjusted until the required composition is attained. A very useful review of reactive sputtering, covering both the mechanisms and the primary reactive sputtering techniques, has been given by *Westwood* [29.61].

Co-sputtering has certain advantages from the point of view of the preparation of films whose components

have different sputtering yields. Segregation of components on cooling can lead to a nonstoichiometric composition of material in the target, and differences in sticking coefficients between components can lead to the deposited composition differing from that arriving at the substrate. Co-sputtering has the advantage that the proportion of each sputtered components may be controlled during deposition, and may readily be adjusted in response to varying conditions to ensure stoichiometry of the deposited film. Co-sputtering may be performed with two or more conventional sputtering targets operating simultaneously for each component, each directed towards a common substrate. Another method of co-sputtering is again to use conventional targets, but with the substrate alternately subjected to the sputtered material from each target. This may be achieved by mounting the substrate on a disc which rotates in front of the targets. Alternatively a specially designed target assembly may be used such that the components arrive at the substrate in their stoichiometric proportions; the potentials of the components may be independently controlled to compensate for differing sputtering yields and sticking coefficients. Generally a plane-parallel substrate arrangement, with the target large in comparison to the target-substrate distance is employed, which maximises the uniformity of the film thickness. *Sinclair and Peters* [29.62] have described some target-electrode assemblies which have proven suitable for co-sputtering, including a concentric ring and disc assembly and an interdigitated design. Each of these allows independent control of the voltage applied to the two parts of the electrode assemblies and thus control over the composition of the sputtered films. Although the spatial dependence of the electric field in such assemblies is complex, and the deposition rate of one component may be influenced by the potential applied to the electrode for the other component, it is relatively straightforward to calibrate such a source for different materials, and to compensate for such effects by varying the acceleration potentials accordingly.

It is clear that, in general, impurities present in the gaseous phase may be incorporated into the deposited films. The fraction f_i of the impurity species i trapped within a film is given by [29.57]

$$f_i = \frac{s_i N_i}{s_i N_i + N_R} \quad (29.32)$$

where s_i and N_i ($\text{m}^{-2} \text{s}^{-1}$) are respectively the sticking coefficient and impingement rate of the impurity species and N_R is the molecular deposition rate of the required film material; f_i can be reduced by increas-

ing N_R , or by decreasing either or both of s_i or N_i . In *bias sputtering* the phenomenon of re-sputtering is employed, i. e. components of the sputtered film are re-sputtered by ions from the plasma. This is achieved by applying an additional small negative potential to the substrate. Preferential sputtering of the impurities takes place, providing the binding energy of the impurities is lower than that of the host film material. This leads to an effective reduction in f_i , below that predicted by (29.32) [29.63]. The value of s_i in the expression is effectively reduced by re-sputtering of impurities from the film surface. *Asymmetric alternating current (AC) sputtering* [29.64] achieves similar objectives to bias sputtering, i. e. bombardment of the cathode target by ions to cause sputtering and bombardment of the films by lower-energy ions to preferentially re-sputter the impurities. These are accomplished by establishing an alternating current between the substrate and cathode and the use of a simple diode-resistance network. During the negative half-cycle the full negative potential is applied to the cathode, allowing sputtering to take place. In the following positive half-cycle, a relatively small positive potential (limited by the resistance) is applied to the cathode. This allows low-voltage sputtering of the films, which is sufficient to remove only the gaseous impurities. In this technique, again the value of s_i is effectively reduced, leading to a decrease in f_i . In *getter sputtering*, the gettering action of a freshly deposited thin film is utilised to purge the chamber of unwanted active gases. The concentration of impurities in thin films has been observed to decrease as the film thickness increases, and is attributed to the trapping (or gettering) action of the film material. In getter sputtering systems this action is exploited so that the majority of impurities are trapped in a film region deposited between the gas entry point and the substrates, while the required film is deposited elsewhere in the chamber where the gas impurity concentration will already have been depleted by the gettering action. The design of a typical getter sputtering system is described by Theuerer and Hauser [29.65]. In the case of getter sputtering, N_i is effectively reduced in (29.32), lowering the value of f_i .

Trapping of inert gas molecules in the films is also a possibility, and their concentration should be given by (29.32). However, at thermal energies the sticking coefficient is effectively zero, and thus trapping ought not to be of great concern. Nevertheless, for sputtering systems using argon, concentrations of 0.1% have been observed [29.67], generally for ion energies greater than 100 eV. Although not a major problem for many appli-

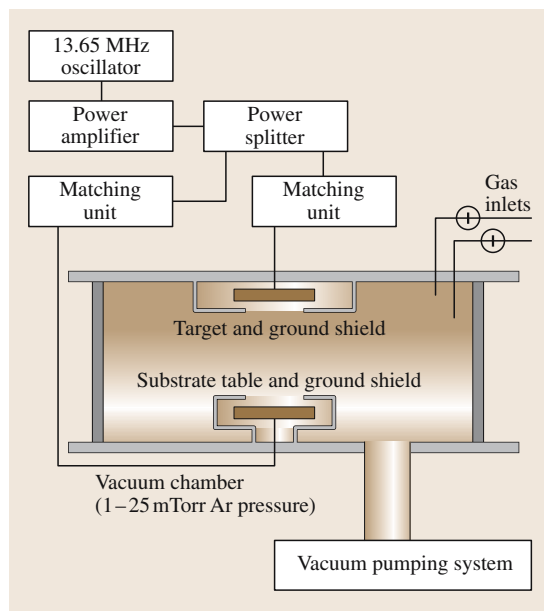

Fig. 29.6 A typical radio-frequency (RF) sputtering system. After [29.66] with permission from Oxford Univ. Press

cations the possibility of inert-gas contamination should not therefore be discounted.

It has been mentioned earlier that simple direct current (DC) discharges as used in the diode and triode sputtering techniques described above, are unable to deposit insulating films. Although reactive sputtering may be used, the deposition of films by this method requires careful control of sputtering rates and gas pressure, and often calibrations of individual systems and materials. The use of *radio-frequency (RF) sputtering*, allows insulators to be sputtered directly [29.68]. When a high-frequency (typically several MHz) alternating signal is applied to a metal plate, on which an insulating (dielectric) target is mounted and is placed within an auxiliary low-pressure discharge, the positive charge which accumulates on the target is neutralised during half of each cycle. Owing to the much higher mobility of the electrons than the ions in the plasma, the plasma potential becomes positive with respect to the target. RF sputtering was first employed by Davidse and Maisel [29.69], who found that a self-sustained discharge could be started and maintained by the application of RF power to the electrode only. The mechanism by which sputtering takes place requires the frequency to be in the radio-frequency range [29.16]. The electron mobility is several orders of magnitude greater than that of the ions

which have difficulty in keeping up with the field variations, and at high frequencies the ions accumulate in front of the target, in the same way that they do in a DC discharge. Because the number of electrons arriving at the target during the positive half-cycle are not matched by the number of ions arriving during the negative half cycle, the front of the target acquires a negative charge, which repels most of the electrons that would arrive at the surface during the positive half-cycle. The plasma itself is said to be positively *self-biased* with respect to the target. It is therefore possible to both feed energy into the plasma, while also giving the ions sufficient energy to cause sputtering. The RF discharge is self-sustained, and Davidse and Maissel found that an externally generated plasma is not required. A schematic diagram of the RF sputtering equipment is shown in Fig. 29.6 [29.66] while more detailed discussion of the RF sputtering process is given in previous reviews [29.16, 57]. These authors point out that a major difference between diode and RF sputtering is a requirement for an impedance matching network or *match box* [29.70] in the RF case. The matching network is inserted between the power supply and the discharge chamber, its purpose being to maximise the power that can be delivered to the plasma. Typically a network containing an inductor and a capacitor is used. An example is shown in the literature [29.71]. A blocking capacitor is normally inserted in the network to ensure that the build up of the self-bias voltage proceeds satisfactorily. Although the target itself will normally perform this function in the case of insulator sputtering, the inclusion of a blocking capacitor allows RF sputtering to be used for the deposition of conductors as well as insulators, so semiconductors and metals are also easily deposited by this technique. Mainly for this reason RF sputtering has become a versatile technique which is used near-universally for semiconductor production as well as for insulators and metals [29.70]. A significant increase in the sputtering rate is also observed in RF systems.

Finally, a technique used to increase the sputtering rate still further is that of *magnetron sputtering*. In this technique, a magnetic field is applied between the target and the substrate. Electrons in the plasma then experience the Lorentz force from the magnetic field in addition to that derived from the electric field, so that the total force on the electron is given by

$$\mathbf{F} = m \frac{d\mathbf{v}}{dt} = e\mathbf{E} + e\mathbf{v} \times \mathbf{B}, \quad (29.33)$$

where \mathbf{F} is the total force experienced by the electron, m and e are the electron mass and charge respectively,

\mathbf{v} is the electron velocity, \mathbf{E} is the electric field and \mathbf{B} is the magnetic field [29.19, 72]. The effect of the two fields is to cause the electrons to move in spiral rather than linear paths, and therefore to greatly increase the distance travelled by the electrons in the plasma. This substantially increases the time the electrons are within the plasma, and thus the probability of their causing secondary ionisation is also significantly enhanced. In turn this leads to increased current flow and crucially increased deposition rates. The magnetron sputtering source is constructed by mounting a powerful magnet below the target, with one pole concentric with the other as shown in Fig. 29.7 [29.66]. This establishes a magnetic field across the target surface; the direction of the magnetic field is perpendicular to the electric field at the furthest extent of the magnetic force lines from the target. The result of the two interacting fields is to confine the electrons for a significant period within a region termed the *racetrack* at the surface of the target, where the electrons effectively hop across the surface. Ionisation of the sputtering gas occurs mainly above the racetrack, and erosion of the target takes place preferentially in this region. In addition to the enhanced deposition rate, magnetron sputtering also has several other advantages. Since the ionisation region is effec-

Fig. 29.7 The technique of magnetron sputtering, showing the hopping electrons of the target confined to a *racetrack* region by the magnetic fields from the magnets under the target. After [29.66] with permission from Oxford Univ. Press

tively confined to the racetrack, unwanted sputtering from the substrate and the walls of the chamber are reduced, as is the substrate temperature. The gas pressure required to sustain the discharge is also reduced, owing to the greater ionisation efficiency.

A further improvement in the technique of magnetron sputtering may be obtained by the use of an unbalanced magnetron, as described by *Window and Savvides* [29.73]. In spite of its excellent high deposition rate, magnetron sputtering generally produces films which have a columnar structure. This leads to the presence of voids, both within grains and at grain boundaries. Low-energy ion bombardment has been shown to improve adatom mobility, allowing atoms to migrate on the depositing surface and filling some of the voids [29.72]. Various computer simulations described in this reference have illustrated the importance of ion beams in depositing dense, void-free films. It is possible to generate an ion current in the plasma by using an unbalanced magnetron where the inner and outer magnets are deliberately unbalanced from the ideal magnetron configuration. Further details concerning the field characteristics of unbalanced magnetrons and of the unbalanced magnetron technique are given in the literature [29.72, 73]. The method has been used to successfully deposit various types of film, including those intended for electrical and optical applications, corrosion protection, and wear and abrasion resistance. A fuller discussion of materials prepared using this method is given by *Rohde* [29.72].

Magnetron sputtering may also be used in conjunction with other sputtering techniques. A combination of RF and magnetron sputtering is frequently used, for example for Co:M alloys where M represents Al, Si, Ti, Cr, Fe, Ni, Cu, Zr, Nb, Mo, Ag, Ta or W [29.74], and also for the deposition of silicon nitride films [29.60].

Thus sputtering has developed from a relatively simple DC technique capable only of the deposition of conductors at a relatively low rate, to encompass both conductors and insulators (RF sputtering) and with sputtering rates suitable for high-throughput industrial processes (magnetron sputtering). Improvements in film morphology have been accomplished by the use of unbalanced magnetron sputtering.

29.1.2 Chemical Deposition Methods

There are many different chemical methods for preparing thin films, but by their nature many of these are restricted to one or perhaps a few different materials, related to a specific chemical reaction or series of reactions. It is therefore only possible to categorise some

general techniques and to give examples for various particular materials. *Campbell* [29.75] divided chemical methods into two classes: those depending on an electrical source of ions, such as electroplating and anodisation, and those requiring a chemical reaction, usually, but not exclusively involving a chemical vapour as in the CVD method. A further technique, which has found favour in recent years, is the deposition of molecular films using the Langmuir–Blodgett technique. Brief examples of these are given below.

Electrodeposition

By electrodeposition, we include all methods which involve passing an electric current through a solution such that a film of a material, usually a metal or an oxide, is deposited on one of the electrodes immersed in the solution. Electrolytic deposition, or *electroplating*, is the deposition of a metal by this method. According to *Campbell* [29.75, 76], of the 70 metallic elements, 33 can be electroplated successfully, although of these only 14 are deposited commercially. The metallic film is deposited on the cathode, and its thickness and the time in which this occurs are determined by the two laws of electrolysis:

1. The mass of the deposit is proportional to the quantity of electricity passed.
2. The mass of material deposited by the same quantity of electricity is proportional to the electrochemical equivalent, E .

This can be expressed as

$$\frac{W}{A} = JtE\alpha, \quad (29.34)$$

where W is the mass deposited on a cathode of surface area A , J is the current density, t is the time of deposition and α is the *current efficiency*, or ratio of the expected to the theoretical mass deposited. Its value is generally in the range 0.5–1.0. The previous expression can be rewritten in terms of the film deposition rate, R (or thickness d per unit time t), by noting that the film density $\rho = W/Ad$. Combining this with (29.34) gives

$$R = \frac{d}{t} = \frac{JE\alpha}{\rho}. \quad (29.35)$$

When a high current is passed through a suitable electrolyte, metallic ions move towards the cathode under the influence of the applied electric field. The mass deposited, and the deposition rate are given by (29.34) and (29.35), and may easily be estimated if E and ρ are known. These are tabulated for the 14 metals commonly

deposited by this method [29.75]. Deposition rates can be very high, depending on the current drawn through the electrolyte. For example, silver will deposit at a rate of about 1 nm/s for a current density of 10 A/m², rising to 1 μm/s at 10 000 A/m² [29.75]. Further details of the deposition of alloys are given in a standard text [29.77], while the growth and structures of electrodeposits are described by *Lawless* [29.78].

A second technique which is used for the deposition of oxides (or less commonly for other compounds such as nitrides), is that of *anodisation*. As its name implies, films are deposited on the anode of the parent metal, following a chemical reaction. The chemical equations describing the anodisation process are given below [29.75]:

where M represents the metal and n is an integer specifying the oxide deposited. The oxide grows in an amorphous form at the metallic anode surface, while hydrogen is evolved at the cathode. The electrolyte is typically an aqueous solution of water containing a dilute acid.

In general a constant current is passed through the cell and film thickness is proportional to the time elapsed. Films grown under constant-voltage conditions, show a decreasing deposition rate with time, as the current falls to zero when the voltage dropped across the film increases to the total applied voltage. Thus the maximum thickness of the film is determined by the voltage used. Growth rates for anodic films under constant-current conditions are of the same order as those for the *PVD* methods of evaporation and sputtering. Aluminium and tantalum anodisation at a current density of 20 A/m² gives growth rates of the order of 1 nm/s [29.76]. Considerably more detailed discussions of anodic oxide films in particular are given in the literature [29.79, 80]. These cover considerably more details of the types of films that may be successfully prepared, their structures, characterisation methods and copious references to related work.

Chemical Vapour Deposition (CVD)

Chemical vapour deposition is a method whereby a volatile compound reacts, with other gas species, to produce the required compound on the substrate. *CVD* does not require operation under vacuum, as with the *PVD* processes of evaporation, *MBE* and sputter-

ing. Moreover, it is capable of producing both silicon and gallium arsenide (GaAs) semiconductor films, and to grow these on substrates of the same material as high-quality epitaxial layers (homoeptaxy). For these reasons it has found wide acceptance in semiconductor processing. High deposition rates relative to *PVD* deposition methods are possible, and controlled doping performed during the deposition process is relatively straightforward. Objects having quite complex shapes can be coated relatively easily, since the film deposition does not depend on line-of-sight geometry as in the case of evaporation and to a lesser extent sputtering. There are however some formidable disadvantages with the technique. Generally much higher substrate temperatures are required in *CVD* than for the other methods. The reactive gases used in the deposition process and/or the reaction products can be extremely toxic, explosive or corrosive, requiring considerable investment in safety features. This may well be justified in high-throughput semiconductor production processes, but uneconomic for smaller-scale development work, where *PVD* methods are preferable. Corrosion and effects of unwanted diffusion, alloying and chemical reactions at the substrate surface may occur under the high operating temperatures, and masking of substrates is particularly difficult [29.81].

In principle *CVD* may utilise any chemical reaction which produces the required material, and therefore the equipment used for the production of a given material is likely to differ from that required for another material. Nevertheless, there are several different classes of reaction which are used in *CVD* processes which are described in the literature [29.16, 18, 19, 75, 76]. Some of these are outlined below.

Pyrolysis or thermal decomposition of a gaseous compound entails passing a vapour over a heated substrate, which causes decomposition and the condensation of a stable solid. This has been used primarily in the production of silicon from SiH₄ and nickel from nickel carbonyl. *Oxidation* is frequently employed to provide SiO₂ in silicon processing. Halides of the required metal oxide are reacted with steam to give the oxide and a hydrogen halide. In *nitriding* the steam is replaced with ammonia (NH₃), and nitrides such as Si₃N₄ may be generated. *Reduction* reactions use hydrogen gas instead of steam or ammonia in the preparation of silicon and refractive metals such as tantalum or molybdenum from their halides. In *disproportionation*, a reversible reaction of the type

is usually employed [29.76], where A represents a metal, B is usually a halide and both AB and AB_2 are gases. The higher valence state is more stable at lower temperatures so, if the hot gas AB is passed into a colder region, AB_2 will be formed and A deposited. In *transfer reactions* for the preparation of compounds, two different strategies may be employed. Either a compound can be used as the source material, or the source comprises a volatile compound of one of the elements of the required compound. Gallium arsenide (GaAs) can be prepared by both methods [29.16, 83]. In Fig. 29.8 [29.82] a typical CVD system is shown which uses a transfer reactor of the second type to produce GaAs. Highly purified arsenous chloride ($AsCl_3$) and Ga are the source materials. Purified hydrogen is bubbled through the $AsCl_3$ and passed through the furnace. In zone 1 of the furnace, the following reaction takes place:

The arsenic vapour is completely absorbed by the Ga source in zone 2 until saturation occurs at 2.25 at. % As. No free arsenic condenses beyond the furnace, but gallium is transported as a lower chloride. Deposition of GaAs occurs in zone 3, when hydrogen is diverted to bypass the bubbler.

Tables of materials which can be deposited by CVD and the associated reactions are given in the literature [29.19, 75]. However, several modifications to the basic CVD process are also in current use. These seek to overcome some of the deficiencies associated with CVD, such as the operation at atmospheric pressure and the use of very high temperatures often involved. Systems employing organic precursors also have certain advantages for the deposition of various materials.

We first discuss low-pressure CVD or LPCVD. Typical pressures of the order of 100 Pa are used, approximately a thousandfold reduction from atmospheric pressure. Contamination is normally lower than for atmospheric CVD and film stoichiometry is often improved. To compensate for the reduced pressure, the input reactant gas concentrations are increased, the gas flow velocity is increased, but the gas density is reduced. Because the mean free path of the gas molecules increases due to the reduced pressure, substrates can be placed closer together, giving a higher throughput in commercial applications. Silicon and dielectric films are generally prepared by this method. The operating temperatures required for LPCVD remain high, however.

In plasma-enhanced CVD (PECVD) a glow discharge is initiated inside the chamber where the reaction occurs. A comprehensive review of the PECVD technique is given by Ohja [29.84]. Dissociation of the gas in the plasma takes place, owing to the nonequilibrium nature of the plasma, which has a high electron temperature but a low gas temperature. The main advantage of this technique is that the plasma decomposition allows film deposition to take place at much lower temperatures than those employed in atmospheric CVD using decomposition reactions and also in LPCVD. In PECVD, as in LPCVD, the pressure is reduced considerably below atmospheric pressure, although the range of pressures employed varies over a wider range, and can be as high as a few hundred Pa. The discharge is usually excited by an RF field, although both DC and microwave frequency fields have also been used. Average electron energies are of the order of several eV, which is sufficient to cause ionisation and decomposition of the gas molecules. A major application of PECVD is in the deposition of silicon nitride films, an important dielectric used in semiconductor processing for microelectronic

Fig. 29.8 Epitaxial growth apparatus for the production of GaAs using chemical vapour deposition (CVD). After [29.82] with permission from Elsevier Science

passivation. Here the temperatures may not exceed about 300 °C, otherwise damage to the circuitry can result, and so atmospheric CVD and indeed LPCVD are not suitable techniques. For details of the chemical reactions involved, and a comparison of the properties of silicon nitride prepared by LPCVD and by PECVD the reader is referred to the literature [29.19, 85]. The former reference also includes a table giving details for the deposition of many other thin-film materials, including silicon, germanium and other semiconductors, as well as various oxides, nitrides and carbides. PECVD systems operating at microwave frequencies utilise the phenomenon of electron cyclotron resonance (ECR); this deposition method is known as electron cyclotron PECVD (or ECR-PECVD). Frequencies are of the order of 1–10 GHz and the ECR plasma may be generated at pressures of about 10^{-3} – 10^{-1} Pa, leading to a degree of ionisation up to about 1000 times that achieved in an RF plasma [29.19]. High deposition rates, low-pressure operation and absence of contamination have made ECRPECVD a very attractive technique for film deposition. A full review of this technique has been given by Popov [29.86].

Finally we briefly mention the technique of metalorganic CVD (MOCVD),

which is becoming an increasingly important method of film deposition. The technique is essentially the same as CVD, except that at least one of the precursors is a volatile metalorganic compound, such as a metal alkyl. The formation of the required compound takes place by pyrolysis of the metalorganic compound with another (inorganic or organic) gaseous precursor. The main advantage of MOCVD is the relatively high volatility of the organic compounds at moderate temperatures, and the fact that, since all these are in the vapour phase, precise control of gas flow rates and partial pressures are possible [29.19]. The compound semiconductors such as GaAs, GaP and InP may be prepared using, for example, trimethyl-Ga [(CH₃)₃Ga] or trimethyl-In [(CH₃)₃In] as precursors. The basic reaction is with a Group V hydride, e.g. AsH₃ or PH₃ for the compounds listed above. A short table of some film materials which have been successfully generated by MOCVD is given in the literature [29.19]. In addition to its applications in preparing compound semiconductor films MOCVD has also been applied to the deposition of high-temperature superconducting thin films, with quite complex structures [29.88].

Langmuir–Blodgett Film Deposition

The Langmuir–Blodgett technique of film deposition entails the coating of solid substrates with molecular

Fig. 29.9a–d Langmuir film deposition: (a) immersion of a hydrophilic substrate without film deposition; (b) withdrawal of the hydrophilic substrate; (c) repeated immersion with film deposition; (d) continuation of the process. After [29.87] with permission from Elsevier Science

layers. Langmuir [29.89] first described the transfer of fatty-acid organic monolayers from the surface of water to a rigid substrate, while Blodgett [29.90] extended the work to show that the process could be repeated so that monolayers were sequentially transferred to form multilayer films. The early history of Langmuir–Blodgett films has been briefly described in the preface to the Proceedings of the First International Conference on Langmuir–Blodgett Films [29.91]. In the basic deposition process, a fatty-acid film is spread over the surface of a subphase (usually purified water). Most molecular-film materials have a molecular structure where one end of the molecule is hydrophilic, which seeks out the water subphase, while the other end of the molecule is hydrophobic and attempts to point away from the water subphase. We therefore have the situation where the hydrophilic end of the molecule is oriented downwards towards the water, with the hydrophobic end oriented upwards. In Langmuir–Blodgett deposition, the required molecules are dispersed in a volatile solution, which eventually evaporates, leaving the molecules with their hydrophilic ends immersed in the water, but with their axes randomly oriented [29.87]. A compressive surface-barrier system is employed to compress the molecules so that they are close-packed and oriented perpendicular to the surface of the subphase, with their hydrophilic ends pointing vertically downwards. The molecules can then be transferred to either a hydrophilic or hydrophobic substrate by slowly dipping into the subphase. The basis process is shown in Fig. 29.9 [29.87], for the case of a hydrophilic substrate. On the initial introduction of

Fig. 29.10 The pressure–area relationship for a cadmium stearate molecular layer obtained at a temperature of 22 °C at pH 5.6. Film deposition should be carried out in the linear region of the curve, i. e. the region of complete condensation without collapse. After [29.87] with permission from Elsevier Science

the substrate into the subphase no coating takes place (a), but on removing it a film attaches to the substrate by polar-bond formation (b). The substrate is then effective hydrophobic, and on dipping for a second time, the hydrophobic ends of the molecules on the subphase form van der Waals bonds with the hydrophobic substrate surface, thus again making the surface hydrophilic (c). On withdrawing the substrate for a second time a further molecular layer is deposited, with the hydrophobic ends of the molecules at the surface (d). Repeated dipping cycles then establish multilayer films with an odd number of layers. The use of an initially hydrophobic substrate gives an even number of molecular layers for each completed dipping cycle.

It is evident that we have a mechanism whereby a predicted number of molecular layers may be deposited, and knowing the molecule dimensions (i. e. the length of the molecule between its hydrophilic and hydrophobic ends) together with the number of dipping cycles, it is easy to accurately calculate the film thickness. It is important, however, that the surface pressure is maintained within a fixed range of values during deposition. If it is too high the surface film collapses in localised regions, giving a transferred layer thickness greater than one monolayer; conversely, if the pressure is too low, there may be voids in the film surface, which transfer on to the substrate. This is illustrated in Fig. 29.10 [29.87], which shows a pressure–area isotherm for a cadmium

stearate molecular layer. It is normal to use a feedback system during deposition to control a moveable barrier on the film surface to maintain the surface pressure within a narrow range while the dipping process takes place. Here the molecular area remains effectively constant for a large change in pressure (region of complete condensation in the figure), ensuring that small changes in pressure do not cause the deposited film to fold over or break up.

There are, however, some limitations to the use of the Langmuir–Blodgett deposition method. The material must satisfy the following requirements [29.87]. The molecular chain structure needs to be hydrophilic at one end and hydrophobic at the other. Furthermore, it should be insoluble in water, but soluble in a suitable solvent in order to give a spreading solution. Some materials which are insoluble can, however, be modified by chemical substitution of molecular end groups. For example, metal-free phthalocyanine is normally insoluble, but the chemical addition of $C(CH_3)_3$ end groups to the molecule renders it soluble in some aromatic solutions such as toluene. This type of chemical modification allows the deposition of materials which cannot normally be deposited to be deposited in a substituted form [29.92]. Many other substituted organic compounds may also be deposited, including dyes, porphyrins, fullerenes, charge-transfer complexes and polymers [29.93]. It is also possible to prepare Langmuir–Blodgett film layers with alternating monolayer structures, by dividing the Langmuir–Blodgett trough into two compartments, one for each type of monolayer, separated by a surface barrier [29.94,95]. Deposition then takes place by alternately removing the substrate from the surfaces of the two compartments, by passing the substrate through the subphase under the surface barrier between deposition of each of the materials.

The advantages of the Langmuir–Blodgett technique over other thin-film deposition methods lie primarily in the low temperature at which deposition takes place (close to room temperature), and on the feasibility of depositing very thin mono-molecular layers of known thickness. Several types of electronic devices incorporating Langmuir–Blodgett films have been discussed [29.96] as has the writing of very fine lines of width less than 10 nm separated by 20 nm in manganese stearate films [29.97]. Further work on the deposition of other materials by this method may well lead to novel device structures and to improved processing methods. An excellent discussion on the preparation and major properties of Langmuir–Blodgett films is given by Petty [29.93].

29.2 Structure

In this section some examples of the structures of various types of thin films are described. By the *structure*, we mean mainly the crystallographic form in which the film is deposited, and also factors associated with this, such as the mean size of crystallites and their orientations. However, the gross morphology of films is also included, and this covers features generally larger than the grain size. The basic type of film, i. e. epitaxial, polycrystalline or amorphous, is usually deduced by diffraction methods (X-ray, electron or neutron), although we will mainly be concerned with the first of these only. Thus a brief description of the method of X-ray crystallography is first given, followed by examples of different types of films that have been observed. Finally some examples of the larger-scale morphology are described.

Several reviews of film structure have been given previously [29.98–100], as well as more generalised discussions in most of the texts covering thin films, to which the reader is referred. However, it should be noted that the large number of variables encountered in thin-film deposition processes (e.g. substrate temperature, deposition rate, angle between vapour stream and substrate) permit films of differing structures to be deposited under nominally similar conditions. It is always wise, therefore, before interpreting measurements of any thin-film properties (such as the electrical or optical properties) to first fully determine the structure of the films, and to take this into account in any interpretation.

29.2.1 Crystallography

In general films tend to deposit from the vapour phase in one or more of their documented bulk-crystal structures. In crystals, the spatial arrangement of the atoms exhibits a symmetry, which can be replicated throughout three-dimensional space by repetition of a basic unit, called the primitive unit cell. The unit cell of any crystal structure may be specified by the magnitudes of three vectors **a**, **b** and **c** representing the unit cell lengths, and the angles α , β and γ between the three vectors. Symmetry considerations allow all crystals to be classified into seven crystallographic structures, namely the cubic, tetragonal, orthorhombic, hexagonal, trigonal, monoclinic and triclinic forms, of which only the first three are orthogonal. Conditions on the equality or otherwise of the lengths *a*, *b* and *c* and the angles between them determine into which type the structure of a given material falls. In three dimensions the atoms arrange themselves in planes, with gaps between the planes known as the

planar spacing, d_{hkl} . In any perfect crystal there are many sets of crystal planes that may be identified. The possible planar spacings are given by different expressions, depending on the crystal structures. For example, in the cubic structure ($a = b = c$, $\alpha = \beta = \gamma = 90^\circ$)

$$\frac{1}{d_{hkl}^2} = \frac{h^2 + k^2 + l^2}{a^2} . \quad (29.39)$$

In the tetragonal structure ($a = b \neq c$, $\alpha = \beta = \gamma = 90^\circ$)

$$\frac{1}{d_{hkl}^2} = \frac{h^2 + k^2}{a^2} + \frac{l^2}{c^2} \quad (29.40)$$

and in the hexagonal structure ($a = b \neq c$, $c \perp a$, $\gamma = 120^\circ$)

$$\frac{1}{d_{hkl}^2} = \frac{4}{3} \left(\frac{h^2 + hk + k^2}{a^2} \right) + \frac{l^2}{c^2} . \quad (29.41)$$

In these equations *a*, *b* and *c* represent the lengths of the sides of the primitive unit cell, and *h*, *k* and *l* are integers. Similar, but more complex, equations exist for the other crystal structures which have less symmetry. For bulk crystals having unit cell sides of the order of nanometres, the crystal planes act as three-dimensional diffraction gratings, which reflect an incident beam of radiation according to Bragg's law,

$$\lambda = 2d_{hkl} \sin \theta , \quad (29.42)$$

where λ is the wavelength of the radiation, and θ is the angle between the incident beam and the reflecting planes. The values of λ for X-rays, electrons and neutrons may be chosen such that they are of the same order as d_{hkl} , and therefore diffraction will occur at suitable angles. These angles are those which satisfy Bragg's law, and are therefore determined by the radiation wavelength λ and by the integer values (*h*, *k* and *l*) applying to the sets of reflecting planes present. (*hkl*) then specifies the set of reflecting planes, and also the orientation.

For perfect crystals, reflections only occur at certain well-defined angles. If the crystal is rotated with respect to the incident beam of radiation, the deviation angle between the incident and reflected beam is 2θ . If the material, instead of being perfect, is made up of a large number of differently oriented microcrystallites, i. e. it is polycrystalline, the diffraction method will pick up reflections from a large number of individual crystallites, and therefore provide data on all the reflecting planes present. A particular set of planes will only reflect at

a specific value of 2θ , and by observing the reflecting angles the planar spacings d_{hkl} can be determined. By reference to standard tabulated data (such as the *International Tables of Crystallography*), which give details of the reflections and intensities expected for most crystalline materials, a considerable amount of information can be determined. This includes the nature of the phases present, their preferred orientations and a measure of the microcrystallite size.

X-ray diffraction is the most commonly used technique. The penetration depth of X-rays can be quite significant, and if the film is too thin they can penetrate down to the substrate. Thus X-ray diffraction often gives information on the substrate as well as the film. If this is to be avoided, the film thickness needs to be increased or the X-rays directed at a low glancing angle with respect to the substrate surface. Electrons have a considerably lower penetration ability, and therefore give information only on the immediate surface region. Neutron diffraction is used particularly in the investigation of magnetic films.

29.2.2 Film Structure

Apart from the detailed type of crystal structures observed, it is useful to divide the structures of thin films into three main categories, according to their crystallographic perfection (or lack of it). Epitaxial films are essentially perfect films grown on a substrate surface with all the atoms arranged predictably in their correct crystallographic positions. There may be certain defects, such as vacancies, interstitial atoms or impurities, but the deviation from perfection should be relatively small. Furthermore, there may be some slight deviations in the unit cell dimensions from those of the corresponding bulk material, owing to idiosyncrasies of the deposition method or the substrate surface, and in particular to stresses built up in the film during deposition. Various methods have been devised to deposit epitaxial films, such as molecular-beam epitaxy (MBE) and vapour-phase epitaxy, both of which are used in the semiconductor industry for preparation of high-quality films. Non-epitaxial films are frequently polycrystalline, having a large number of grains, oriented in different directions, and separated by grain boundaries. The grain size is heavily influenced by the deposition conditions, and can have a profound effect on secondary properties, such as the electrical conductivity, in which grain boundaries influence the electron mean free path. Finally, amorphous films have no long-range order, being noncrystalline, with only short-range order apparent.

Substrate temperature during deposition and subsequent thermal history after deposition can have a profound effect in determining the initial structure, orientation and subsequent phase changes. Some examples of these effects are included in the following discussion.

In the case of epitaxial films, a large number of factors determine whether the film is indeed epitaxial, and if so the crystalline orientation that will result. The main concepts that underlay the growth of epitaxial films are the equilibrium thermodynamics of the growing nuclei, the evaporation process as described by the Hertz–Knudsen expression (29.5), surface kinetics and mobility on the substrate and the growth of defects [29.101]. The interdependence and interaction of these various processes, which are generally all temperature-dependent, lead in many cases to a particular value of temperature (usually called the epitaxial temperature) only above which epitaxy can take place. Depending on the relative difference between the unit cell dimensions of the substrate and the films (often quantified as the *misfit*) there is frequently a considerable stress between them, which is released by a network of imperfections (dislocations). Details of the epitaxial growth are strongly related to various theories of nucleation. There are several of these, based on the characteristics of microscopic nuclei on the substrate. These grow during the deposition process, and if the conditions are suitable, can result in the deposition of epitaxial films. In the capillarity model [29.9, 27] the nuclei become stable when they reach a particular size (the critical nucleus). Above this size the nucleus is stable and continues to grow. However, in this case the size of the critical nucleus is of the order of 100 atoms or more. An alternative theory of nucleation has been proposed for critical nuclei consisting of only a few atoms [29.102, 103]. In this model certain geometries have been postulated for the critical nucleus under different conditions of supersaturation and substrate temperature. The rate of nucleation is given by

$$I = Ra_0^2 N_0 \left(\frac{R}{\gamma N_0} \right)^{n^*} \times \exp \left(\frac{(n^* + 1)Q_{ad} - Q_D + E_{n^*}}{k_B T} \right). \quad (29.43)$$

In this expression the symbols have the following meanings: R is the impingement rate of atoms on the substrate, a_0 is a characteristic jump distance of the atoms across the substrate surface, N_0 is the concentration of adsorption sites, $\gamma = h/k_B T$ is the vibrational frequency, where T is the substrate temperature, and n^* represents the

number of atoms in the critical nucleus. The remaining terms in the numerator of the exponential represent energies: Q_{ad} is the binding energy of a single atom to the substrate surface, Q_D is the activation energy for surface diffusion of adsorbed atoms and E_{n^*} is the dissociation energy of a critical nucleus containing n^* atoms. By substituting $n^* = 1, 2, 3$, etc., into (29.43), expressions can be obtained for critical nuclei of size 1, 2 or 3 atoms. These correspond to stable nuclei of size $(n^* + 1) = 2, 3$ or 4. By simultaneously solving pairs of these equations, it is possible to calculate the temperature at which the size of the critical nucleus changes from one value of n^* to another. For example, the temperature at which the critical nucleus size changes from one to two atoms, T_{12} , is given by

$$T_{12} = -\frac{(Q_{ad} + E_2)}{k \ln(R/\gamma N_0)}, \quad (29.44)$$

where E_2 is the dissociation energy of a two-atom nucleus into single atoms. The model has been tested, notably in the case of a face-centred cubic metal (silver) deposited on a high-purity (100) NaCl substrate [29.103]. At low substrate temperatures and high supersaturations, it was found that the nucleation rate I is proportional to R^2 , which from (29.43) implies that $n^* = 1$ (the critical nucleus is just one atom). At higher temperatures, critical nuclei were found to have $n^* = 2$ or 3, with stable nuclei adopting the (111) or (100) orientations. Further discussion is given in several later reviews [29.1, 10, 16, 19]. More-sophisticated models of

nucleation are based on the kinetic behaviour of nuclei, and involve a set of coupled differential equations, relating growth and dissociation of nuclei. More details are given in the literature [29.105, 106].

Another example of where the occurrence of epitaxy is defined by well-defined temperature ranges, is given in the work of Kalinkin et al. [29.107] Muravjeva et al. [29.104]. This important work has also been discussed in other reviews [29.108, 109]. These workers made extensive measurements on the evaporation of both cadmium and zinc chalcogenides (sulphides, selenides and tellurides), which were evaporated from Knudsen cells at a pressure of about 10^{-2} – 10^{-3} Pa. The substrates used were mica in all cases. It was found that for all three cadmium compounds, and all three zinc compounds, the conditions for epitaxial growth were dependent on both the temperature of the substrate (the epitaxial temperature T_{Ep}) and the evaporator temperature T_{ev} . The latter influenced the evaporation rate N_e (29.5) and also the supersaturation ratio of the growing films. For each of the six compounds, different combinations of T_{Ep} and T_{ev} were investigated. We discuss in detail only the cadmium compounds, although the behaviour of the zinc compounds is entirely similar, as can be seen from Fig. 29.11 [29.104]. Below about $T_{Ep} \approx 310$ – 320 °C, the evaporator temperature for epitaxy T_{ev} increased approximately linearly with T_{Ep} according to $T_{ev} = A_1 + T_{Ep}$, where A_1 is a constant. Above $T_{Ep} \approx 310$ – 320 °C, T_{ev} decreased linearly with T_{Ep} according to $T_{ev} = A_2 - 2T_{Ep}$, where A_2

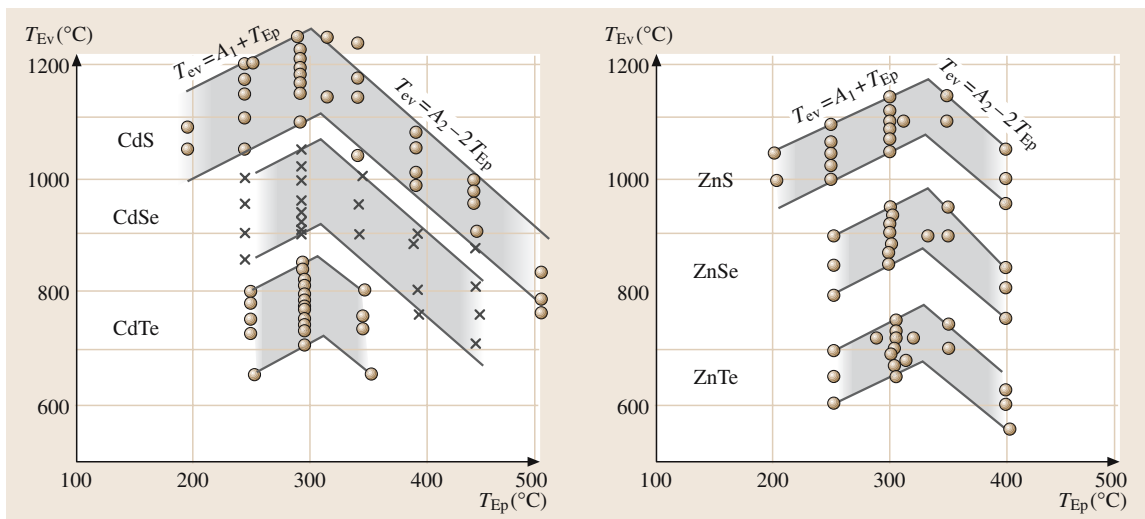

Fig. 29.11 Relationship between the evaporation temperature T_{ev} and the epitaxial temperature T_{Ep} in the growth of cadmium and zinc chalcogenide films on mica. After [29.104] with permission from Elsevier Science

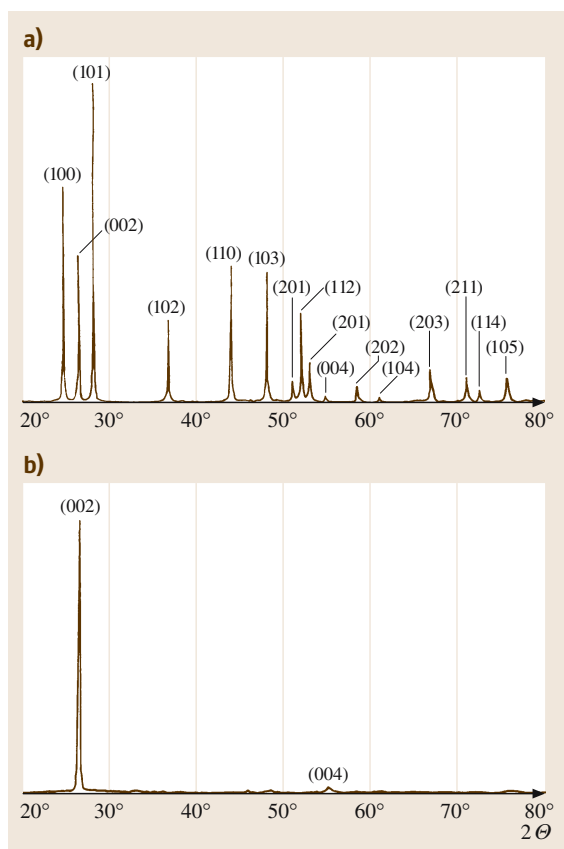

Fig. 29.12a,b X-ray diffraction traces obtained from (a) CdS powder, and (b) a CdS thin film. After [29.110] with permission from Wiley-VCH

is a second constant. These relationships between the epitaxial temperature and the evaporator temperature are illustrated in Fig. 29.11 [29.104]. For the cadmium chalcogenides, values of the range of the constants A_1 and A_2 for which epitaxial behaviour was observed are $A_1 = 800\text{--}950^\circ\text{C}$ and $A_2 = 1750\text{--}1900^\circ\text{C}$ for CdS, $A_1 = 600\text{--}750^\circ\text{C}$ and $A_2 = 1550\text{--}1700^\circ\text{C}$ for CdSe, and $A_1 = 400\text{--}550^\circ\text{C}$ and $A_2 = 1350\text{--}1500^\circ\text{C}$ for CdTe [29.104]. It is evident from these values that for each substance the evaporator temperature T_{ev} lies within a range of about 150°C for values of T_{Ep} at which epitaxy is possible. In addition, for a given substrate temperature the evaporator temperature required for epitaxial CdS is highest, becoming progressively lower for CdSe and for CdTe. For example for $T_{\text{Ep}} = 320^\circ\text{C}$, the evaporator temperatures for epitaxy are $1120\text{--}1270^\circ\text{C}$ for CdS, $920\text{--}1070^\circ\text{C}$ for CdSe and $720\text{--}870^\circ\text{C}$ for CdTe. The same sequence is also followed for the zinc

chalcogenides. At combinations of temperatures outside the limits given by the values of A_1 and A_2 , the films deposited were not epitaxial, being polycrystalline and only partially ordered.

We now consider some examples of polycrystalline thin films, and the factors which account for their various crystallographic characteristics. X-ray diffractometry is particularly useful in determining the basic crystal structure adopted by a particular film, particularly when two or more phases are possible. The cadmium chalcogenides have, on average, four valence electrons per atom, which leads to tetrahedral bonding. However, there are two different ways in which tetrahedra formed from each of the constituent atoms can penetrate into each other. This leads to two allowed crystal structures: the hexagonal wurtzite structure and the cubic zinc-blende structure. The planar spacings for these are described by (29.41) and (29.39), respectively. In the evaporant material, which is usually composed of a polycrystalline powder, a large number of diffraction peaks normally occur, which can be indexed using the appropriate planar spacing expression. Figure 29.12a [29.110] shows an example of a diffraction trace obtained from CdS evaporant powder. The diffraction planes are indexed in terms of the hexagonal structure, and rule out the possibility of the material being of the cubic form. More interestingly, Fig. 29.12b shows a trace obtained from a thin film prepared from this material. Although the two peaks shown correspond to those observed for the evaporant powder, it is clear that reflections from most of the crystal planes are missing. If the intensities of the peaks are different from those for a random powder (or more specifically from those tabulated in the *International Tables of Crystallography*), the crystallites are said to be preferentially oriented. In this case it can be seen that virtually all the crystallites must be aligned in the same direction, with the c -axis directed perpendicular to the substrate plane, along a preferential orientation in the $[002]$ direction.

Apart from the simple determination of film crystal structures and preferential orientations, it is also possible to monitor changes from one crystal structure to another. For example, the phthalocyanines are organic crystals, which are known to possess several basic crystal structures, of which the α -phase and the β -phase are the most common. There is some controversy over whether the α -phase is orthorhombic or monoclinic, and it was originally identified as tetragonal [29.111]. The β -phase is monoclinic. However, X-ray diffraction has identified most films prepared at lower substrate temperatures as being of the α -structure, while those deposited

at higher temperatures are of the β -structure. Both copper phthalocyanine (CuPc) and cobalt phthalocyanine (CoPc) films deposited on to substrates held at room temperature were of the α -structure, but on annealing at 240 °C for an extended period, the CuPc films underwent a phase transition to the β -structure [29.112]; the CoPc films also showed a transition to the β -phase on annealing at temperatures up to 325 °C [29.113]. The α -form films of both materials were preferentially aligned in the [001] direction assuming a tetragonal structure, or the [002] direction assuming an orthorhombic or monoclinic structure. The annealed β -form films were also preferentially oriented, in the [20 $\bar{1}$] direction for CuPc and the [001] direction for CoPc. In the latter case it was possible to monitor the dominant peak over the temperature range 200–325 °C where the phase change occurred. d_{hkl} increased slightly with annealing temperature up to 200 °C, then decreased significantly at 250–300 °C. The value of 2θ decreased slightly with T_{ann} up to 200 °C, again followed by a significant increase at approximately 250–300 °C. For T_{ann} up to 250 °C d_{hkl} lay in the range 1.271–1.277 nm and 2θ in the range 6.92–6.95°, which is close to those expected for α form CoPc; at higher annealing temperatures d_{hkl} was in the range 1.241–1.246 nm and 2θ in the range 7.09–7.12°, which are in better agreement with those expected for β form CoPc.

X-ray diffraction also allows an estimate of the mean grain size L in polycrystalline films to be obtained, by detailed observation of the peak profiles. The well-known Scherrer equation [29.114]

$$L = \frac{K\lambda}{\eta \cos \theta} \quad (29.45)$$

allows an estimate of L to be made from simple details of the peak profiles. In (29.45), λ represents the X-ray wavelength, η the width of a strong peak in radians at half-maximum intensity, and θ is the Bragg angle, where K is a constant which is approximately unity. An example of the use of this method is in the determination of L from the first Bragg peak of α -form CoPc films before annealing [29.113]. The films were subsequently heated to a higher temperature T_{ann} in oxygen-free nitrogen for two hours and the value of L again measured. Measurements were repeated at even higher temperatures until the dependence of L on T_{ann} over the entire temperature range of the α -to- β phase change was determined. These results are illustrated in Fig. 29.13 [29.113]. It is clear that at temperatures up to 200 °C there was an increase in the mean microcrystallite size from about 30 nm to over 40 nm, although there was no indication of a phase

Fig. 29.13 Mean crystallite grain size L as a function of maximum cumulative annealing temperature T_{ann} for a cobalt phthalocyanine film of thickness 0.1 μm . After [29.113] with permission from Wiley-VCH

change. Ashida et al. [29.115] ascribed this effect in CuPc to preliminary crystallite growth at the early stages of the phase transformation process. Above annealing temperatures of about 200 °C there was a rapid increase in crystallite size to about 100 nm at 315 °C; similar behaviour has also been observed in which α -form CuPc films were heated to 300 °C when the diffraction patterns became sharper and the crystallites larger [29.115].

Some general conclusions concerning the dependence of grain size in vapour-deposited polycrystalline films on various film attributes have been summarised by Chopra [29.18]. The major feature determining mean grain size is the surface mobility of adsorbed atoms and clusters during the deposition process. A high surface mobility will allow adsorbed atoms to move large distances before being incorporated into growing nuclei, resulting in a relatively low concentration of nuclei and thus larger crystallites. The substrate temperature is the most obvious factor contributing to high mobility, and therefore grain size tends to increase with increasing substrate temperature. We have already seen that epitaxy requires a minimum substrate temperature; this too is a consequence of the surface mobility requirement. The total film thickness obviously sets an upper limit on the crystallite size, and therefore the grain size increases in general with film thickness. Subsequent annealing at temperatures greater than the substrate temperature during deposition can also cause an increase in the mean crystallite size as was shown in Fig. 29.13, as surface atoms augment the crystallites and grains coalesce.

The dependence of grain size on deposition rate is not consistent between different materials and substrates. Frequently there is an increase with increasing deposition rate [29.18], although a decrease has been observed in some cases, such as in CdTe films where the establishment of a higher concentration of adsorbed nuclei led to the growth of finer grains [29.38].

The interplay between the various deposition parameters can have a profound effect on the structure of the films. This is illustrated particularly well in Fig. 29.14 [29.116], for cadmium arsenide (Cd_3As_2) films evaporated onto mica substrates. Both the substrate temperature T_s and the growth rate v were varied, with the latter covering a wide range. Diffraction patterns indicated that the crystalline films were of the lower temperature tetragonal α -phase of Cd_3As_2 ; the structure of this phase is documented in the literature [29.117] and the planar spacings are given by (29.40). Amorphous films recrystallised following interaction with the electron beam in the electron microscope and also reverted to a tetragonal structure. The figure shows that, over the substrate temperature and deposition rate ranges investigated, the films could have an amorphous, polycrystalline or well-oriented crystal structure. Below approximately 125–145 °C the films were amorphous, with polycrystalline films resulting when this temperature was exceeded. The amorphous-to-crystalline transition was only weakly dependent on the deposition

rate. However, the epitaxial temperature, which delineates polycrystalline and epitaxial films, increased with increasing deposition rate. For deposition rates less than about 4 nm/s (40 Å/s) there was a direct transition from the amorphous to the well-oriented crystalline structure, whereas at higher rates there was a transitional polycrystalline region. The preferred orientation of the films was [001] with the c -axis of the tetragonal structure perpendicular to the plane of the substrate. Also shown on the figure are examples of X-ray diffraction patterns for the crystalline, polycrystalline and amorphous regions. These are characterised, respectively, by discrete reflection points, *spotty* rings and diffuse rings.

Finally, a brief discussion on amorphous films is appropriate. These are films which show no evidence of a regularly repeated crystalline structure, i.e. they do not exhibit long-range order. We have already seen that in Cd_3As_2 films (Fig. 29.14), a relatively low substrate temperature during deposition leads to the growth of amorphous films. This is a general rule, applicable to most materials, and is basically the opposite to the condition for epitaxy – the deposition of amorphous films is encouraged if the surface mobility of atoms on the substrate is low. This causes the adsorbed atoms to be incorporated into the films almost at the point of impact, rather than after diffusion across the substrate surface and joining a growing nucleus. High deposition rates also predispose atoms to remain at their impact position

Fig. 29.14 Effects of film growth rate v and substrate temperature t_s on the structure of Cd_3As_2 films vacuum-evaporated onto mica substrates. After [29.116] with permission from Elsevier Science

within the growing film – they have only a very limited time to diffuse before they are locked into the growing film structure. These considerations are pertinent to the deposition of amorphous metallic films, which require substrate temperatures to be lowered to liquid-nitrogen temperature or below, and also to elemental chalcogenide and semiconductor films (Ge and Si) and carbon, all of which have a sufficiently low surface mobility at room temperature. A table giving examples of amorphous thin film materials, their preparation methods, and the transition from the amorphous to a crystalline phase is given by *Maissel and Francombe* [29.16]. The amorphous state is metastable, requiring some thermal energy to transfer it to a crystalline state.

Another method of producing amorphous films is the incorporation of residual gases during deposition. A relatively high pressure of oxygen ($\approx 10^{-3}$ Pa) can cause oxidation of the evaporant. Large-scale crystallites of metals are then unable to form. The admission of nitrogen during sputtering of refractory metals is also sufficient to result in the deposition of an amorphous phase [29.1].

Since the structure of amorphous materials do not possess any long-range order, it is necessary to describe the short-range order using some function which can be determined directly from diffraction experiments. The radial distribution function $J(r)$ is defined as the number of atoms lying at a distance between r and $r + dr$ from the centre of an arbitrary atom at the origin [29.119]. It is given by

$$J(r) = 4\pi r^2 \rho(r). \quad (29.46)$$

Here, $\rho(r)$ is an atomic pair correlation function, which is equal to zero at values of $r < r_1$, where r_1 is the average nearest neighbour interatomic separation, $\rho(r)$ is equal to the average value of density ρ^0 at large values of r where the material becomes homogeneous. Between these values $\rho(r)$ is oscillatory, with the peaks in the distribution corresponding to the average interatomic separations [29.119]. $J(r)$ also shows oscillations superimposed on the average density parabola $4\pi r^2 \rho^0$, and the area under a particular peak gives the co-ordination number for the given shell of atoms. The coordination number represents the number of nearest neighbours in the structure. An example of a radial distribution function, derived from X-ray data, for thin films of the compound $\text{Ge}_x\text{Te}_{1-x}$ where $x = 0.11$, is shown in Fig. 29.15 [29.118]. For materials having covalent bonds the coordination number is four, whereas for amorphous metals, which generally crystallise in close-packed structures, the coordination number is higher.

Fig. 29.15 Calculated radial distribution function for a sample of composition $\text{Ge}_{0.11}\text{Te}_{0.89}$. The dashed curve represents the contribution of the average electron density. After [29.118] with permission from Elsevier Science

For covalently bonded materials, the atoms tend to arrange themselves in tetrahedra, which in the amorphous state interconnect at their apexes. However, the apexes themselves interconnect within the material in a random manner, whereas the tetrahedra dimensions are effectively determined by the size of the atoms. Thus there is no long-range order because of the random interconnections, but the short-range order survives, and is similar to that for the corresponding crystalline material. *Bosnell* [29.120] has described the important amorphous semiconducting thin films, and classified them into three major categories: covalent noncrystalline solids, semiconducting oxide glasses and dielectric films. The importance of these materials, in particular their electrical properties, cannot be overestimated. The standard text on this subject [29.121] gives copious information on their electrical properties, as well as their structures and radial distribution functions. Local atomic order in amorphous films is discussed in the literature by *Dove* [29.122], with the primary emphasis being on data derived from electron diffraction. This work also gives the theory behind the radial distribution function, and provides a wide review of radial distribution functions measured in many systems performed prior to the date of the review.

From the foregoing discussion and examples, it should be clear that the crystallographic structure of thin films, whether epitaxial, polycrystalline or amorphous, depends heavily on the deposition conditions. In turn

the film structure strongly influences the mechanical, thermal, optical and electronic properties.

29.2.3 Morphology

Perhaps the most striking morphological characteristic observed in thin films grown by the physical vapour deposition techniques is that of the columnar grain structure. Electron microscopy frequently reveals that high-density regions tend to grow in parallel columns. They tend to develop when the surface mobility of adsorbed atoms is relatively low, so that the area of the base of the columns is small. Further growth of the grains is away from the substrate. The direction of column growth is not necessarily perpendicular to the substrate surface, although it frequently is for depositing material arriving at normal incidence. For oblique incidence it has been observed that the columns are oriented away from the substrate normal and towards the vapour source, although not necessarily pointing directly towards it. If α is the angle between the substrate normal and the vapour stream, and β is the angle between the substrate normal and the direction of the columns, it has been shown experimentally that β is usually less than α . The tangent rule [29.124] relates these two angles and is given by

$$\tan \alpha = 2 \tan \beta \quad (29.47)$$

and was found to be followed for the case of directly evaporated aluminium. In experiments on CdS films, Hussain [29.125] deposited films of thickness up to 100 μm with angle of incidence α varying between 0 and 60°. Up to a certain film thickness the c -axis of the grains was perpendicular to the direction of vapour incidence, but above this thickness the c -axis started to shift towards the substrate normal, eventually becoming aligned with it. Etching of a thin film deposited at oblique incidence confirmed that the top layers of the film had their c -axis normal to the substrate, whereas in the bottom layers it was parallel to the direction of vapour incidence. In other work on this material [29.126] similar thickness-dependent orientation effects have been reported. In this case, films of thickness a few tens of nanometres had randomly orientated crystallites, while those of thickness of about 20 μm were aligned with the c -axis normal to the substrate.

Evaporated CdS films also show an interesting morphology on a somewhat larger scale, which is illustrated in Fig. 29.16 [29.123]. This illustrates features which are evident in many different types of thin films. The top surface of as-deposited films of thickness 25–30 μm were observed by scanning electron microscopy to consist of

Fig. 29.16 Schematic representation of evaporated CdS film microstructure inferred from scanning electron microscopy studies. After [29.123] with permission from Elsevier Science

partially faceted hills with a height of 5 μm and a width of about 15 μm at the base. These workers also determined the grain size and crystal defect structure using transmission electron microscopy. The grain size was about 2 μm at the top and at the centre of the films, but was only of the order of 10–50 nm at the back surface adjacent to the substrate. Typical dislocation densities were of the order of 10^{13} m^{-2} (10^9 cm^{-2}). Ultrafine-grain regions of 2–15 μm in diameter were observed. These were thought to be spits of material rapidly ejected from the source. Similar features have also been observed in this laboratory [29.110]. The partially faceted protrusions were reported, and cracks in the films were also present, as a result of differential thermal contraction between the CdS films and the glass substrates during cooling. Larger regions of CdS were seen, which were considered to have been ejected from the evaporation boat during deposition. This phenomenon has been referred to as *spattering* or *splattering* by Stanley [29.127], and its elimination is an important goal for deposition processes operating at higher temperatures.

In early work on CdTe films [29.128] photovoltages were measured when there was an angle between the vapour stream and the normal to the substrate. This led to the suggestion that in this case the film growth was directionally anisotropic where the nucleating material depositing on a heated substrate has sufficient surface mobility to form islands rather than a uniform thin film. Additional material arrives at an angle, shadowing the

Fig. 29.17 Schematic three-zone model for the temperature dependence of the growth morphology in evaporated Cd_3As_2 films. T_s/T_m represents the ratio of the substrate temperature to the melting point of Cd_3As_2 . After [29.131] with permission from Elsevier Science

far side of the island from the deposition source, and the shadowed side grows relatively slowly and is well ordered, while the exposed face grows towards the vapour source. When islands begin to touch each other there is expected to be a mismatch, leading to a disordered state in the region between the crystallites. Each interface will therefore have an ordered and a disordered side and at the interface between grains a photovoltage develops. Photomicrographs of epitaxial CdTe layers grown by the close-space technique [29.129] revealed smooth epitaxial layers when the deposition was on to (100), (110) and (111) Cd oriented substrates, but large hillocks grew on (111) Te substrate faces. When grown on mica substrates [29.130] it was observed that the morphology was significantly affected by the composition of the incident vapour phase. This was characterised by the ratios γ_{Cd} and γ_{Te} , which depended on the ratio of the actual concentration to the stoichiometric concentration of the Cd atoms or the Te_2 molecules in the gas phase. When $\gamma_{\text{Cd}} = 53$ when CdTe and Cd were co-evaporated the films were of high quality consisting of large crystallites with degenerated (111) faces. When CdTe and Te were co-evaporated and $\gamma_{\text{Te}} = 12$ formations resembling dendrites were observed.

CdSe film morphologies have been observed by several workers. Tanaka [29.132] prepared films using Ar and H_2 sputtering gases; some films were subsequently annealed in Ar . Microscopic examination showed that sputtering in H_2 gas led to uniform grain growth of the films over the whole substrate surface, while films sputtered and annealed using Ar gave rise to geometric

pillars and a textured structure. An investigation of the optimum conditions for obtaining CdSe epitaxial layers on (0001) oriented sapphire substrates was performed by Ratcheva-Stambolieva et al. [29.133]. For substrate temperatures up to 460°C the layers were polycrystalline, from 460°C to 530°C a small degree of preferred orientation was observed, with a more significant textured structure for temperatures of 530 – 570°C . At higher temperatures of 570 – 620°C a monocrystalline structure was obtained, varying in its degree of perfection depending on the actual temperature and the growth rate. Hexagonal pyramids with peaks, regular or irregular facets and flat tops were also identified. RF-sputtered CdSe films [29.134] were porous when deposited at a substrate temperature of 550°C onto vitreous silica. When deposited onto substrates of single-crystal sapphire the surface appeared shiny, and showed features of hexagonal flat tops and pyramids with edge lengths in the range 1 – $5\text{ }\mu\text{m}$.

We finally look at the morphological characteristics of another cadmium compound, Cd_3As_2 . Evaporated films of this material have been investigated by Jurusik and Żdanowicz [29.131] using electron microscopy. It was found that the microstructure of the films was strongly dependent on the substrate temperature T_s . This type of behaviour is frequently addressed in terms of a zone model, and examples of some of these for other materials are discussed by Ohring [29.19]. In Cd_3As_2 the microstructures were interpreted in terms of a simple three-zone model in which the structure was correlated with the ratio T_s/T_m , where $T_m = 994\text{ K}$

Fig. 29.18 Post-nucleation growth in evaporated Cd_3As_2 films considered as a consequence of two superimposed (planar and thickness) growth stages. After [29.135] with permission from Elsevier Science

is the melting point of Cd_3As_2 [29.131]. They found that for $T_s/T_m \leq 0.4$ the films were amorphous, consisting of spherical or elongated fibrous-like clusters, or were uniform with a large number of pores or cavities. For $0.4 < T_s/T_m < 0.5$ columnar growth was identified, while for $T_s/T_m \geq 0.5$ films with large crystallites and clear grain boundaries were observed. These structures are illustrated in Fig. 29.17 [29.131]. More recently a very detailed study was performed on amorphous Cd_3As_2 films evaporated onto substrates maintained at 293 K [29.135, 136]. It was found that the size of post-nucleation islands was a function of the substrate temperature, type of substrate and the deposition rate. Furthermore the shape and type of growth of the islands varied with these parameters. At a low deposition rate (1 nm/s) the initial nuclei grew until a certain size was reached, and new nuclei started to grow around the original islands. For a moderate deposition rate (3.5 nm/s) the initial nuclei grew into islands which in turn increased in size until the islands had only narrow interfaces between them. Some islands formed polygons. Films deposited at a high rate (50 nm/s) consisted of small islands connected by relatively large low-density areas. Films deposited at low rates were of approximately stoichiometric proportions (i. e. 40 at. % As) while those deposited at higher rates had excess arsenic (typically 51.8 at. % As). It was suggested that the growth process could be considered as a superposition of two growth stages, as shown in Fig. 29.18 [29.135]. The vapour flux onto the substrate is denoted by S_1 and the

adatom flux over the substrate surface by S_2 . In the first stage of growth the initial nuclei enlarge owing to the adatom flux S_2 . The second stage of growth incorporates atoms immediately from the incident flux S_1 . This is usually very slow, but increases as the island surface area increases. At this stage branched complex islands or only compact islands grow as the result of a shadowing mechanism. When the islands touch each other the molecular flux S_2 over the substrate surface is eliminated, and the films grow in thickness as the result of the incident flux S_1 and the structure initiated in the earlier stage (i. e. large branched or smaller compact islands). The final growth structure gives rise to cauliflower-like or columnar structures. In later work [29.136] Cd_3As_2 films were evaporated from bulk crystallites of Cd_3As_2 or CdAs_2 . For films grown from the Cd_3As_2 source a pronounced columnar structure was observed, whereas those evaporated from the CdAs_2 source grew uniformly, and the columnar structure was absent. In the latter case the initial island structure was not observed in the early stages of film growth. It was concluded that prerequisites for columnar growth were a limited surface mobility and an oblique component in the deposited flux, particularly where the films are deposited normally to the substrate surface.

In this section some of the morphological characteristics of some cadmium compound films prepared by PVD methods have been described. The emphasis in this discussion of the films was not primarily because of their usefulness as semiconductors in various applications, but because they exhibit many features typical of a wide range of other film materials. Surface mobility of atomic species on the substrate during deposition is clearly of great importance, as this tends to control the grain size at the substrate interface, while the angle of vapour incidence relative to the substrate normal is an important factor in determining the major direction of crystallite growth and whether a columnar structure develops. Shadowing of the vapour stream by islands during film growth can lead to differential growth rates at different points on the film surface. Bulk diffusion and desorption also contribute to the film morphology variations [29.19]. The morphological characteristics of many materials may be explained using zone models in which the substrate temperature and other variables, such as sputtering gas pressure, conspire to determine the overall morphology via the mechanisms detailed above. The morphology of thin films is particularly rich, and an important factor in influencing film properties.

29.3 Properties

As mentioned in the introduction, the properties covered in this section are restricted to the optical and electrical properties. Moreover, only the very fundamental properties, which are a direct consequence of the thin-film nature of the material, are covered. Thus the more advanced features, such as those exhibited by specific classes of materials, individual elements or compounds, and electronic, optical and optoelectronic devices are not normally discussed, although many of these are considered elsewhere in this Handbook. The basic thin-film properties, which have been exploited in many of these developments are stressed. Examples include the use of thin films in layers or stacks in anti-reflection coatings and mirrors [29.30], the contribution of grain boundaries in conducting thin films to the resistivity of tracks and connections in integrated circuits, the importance of high-field conduction in some electronic devices [29.17], and the possible influence of high-field conduction in nanostructures [29.11].

29.3.1 Optical Properties

This section comprises an introduction to the main optical properties of thin films, starting with a discussion of the properties of nonabsorbing single films at normal and non-normal incidence, and then considering modifications due to absorption. Finally a brief discussion of the use of multilayer film stacks is given. Thin-film optics is a particularly wide field, and readers interested in further details and a more in-depth analysis are referred to one of the standard texts [29.30, 137, 138], or indeed to most general textbooks on optics, nearly all of which cover thin films in some detail. As mentioned earlier, optical effects in thin films were first recorded in the 17th century, which predates by two centuries the emergence of Maxwell's equations, which encapsulate the behaviour of all electromagnetic radiation, including visible light. The boundary conditions at the interface between two different optical media are derivable directly from Maxwell's equations, and allow us to calculate the reflection and transmission coefficients for the amplitude of the electromagnetic wave at the interface. These are termed the Fresnel coefficients.

Figure 29.19a shows the simplest situation, where a beam of light in a medium having refractive index n_0 is incident at an angle φ_0 to the normal on a film of refractive index n_1 . The following expressions for the Fresnel coefficients apply to all individual interfaces in a structure, and for all values of the refractive index. At

this stage in the discussion we assume that the materials are isotropic and nonabsorbing. At the interface the electromagnetic radiation is refracted into the medium of index n_1 at an angle φ_1 , with a reflected component directed back into the incident medium at an angle φ_0 . Conventionally, the coefficients are quoted for components of the light beam resolved parallel (denoted by

Fig. 29.19 (a) Reflection and transmission at a single interface between two media with refractive indices n_0 and n_1 . r_1 and t_1 represent the amplitude reflection and transmission coefficients at the interface (the Fresnel coefficients). (b) Total reflection and transmission as the result of multiple reflection and transmission through a nonabsorbing thin film of thickness d_1 and refractive index n_1 deposited on a substrate of refractive index n_2 . The Fresnel coefficients are indicated at each transit of a boundary, and change sign if the direction of incidence is reversed. R and T represent the total amplitude of reflectance and transmittance, respectively, each obtained by summing the amplitudes of an infinite number of components, although only three are shown

p) and perpendicular (denoted by s) to the plane of incidence. Therefore there are two reflection coefficients r_{1p} and r_{1s} , and two transmission coefficients, t_{1p} and t_{1s} . The 1 in the subscripts in this notation refers to the first interface, i. e. between the materials with refractive indices n_0 and n_1 in this case. More complex systems will have more than one interface, where 2, 3, etc., signify the second or third interfaces. The Fresnel coefficients for reflection are [29.1, 15]

$$\begin{aligned} r_{1p} &= \frac{n_1 \cos \varphi_0 - n_0 \cos \varphi_1}{n_1 \cos \varphi_0 + n_0 \cos \varphi_1}, \\ r_{1s} &= \frac{n_1 \cos \varphi_1 - n_0 \cos \varphi_0}{n_1 \cos \varphi_1 + n_0 \cos \varphi_0}, \end{aligned} \quad (29.48)$$

and those for transmission are

$$\begin{aligned} t_{1p} &= \frac{2n_0 \cos \varphi_0}{n_1 \cos \varphi_0 + n_0 \cos \varphi_1}, \\ t_{1s} &= \frac{2n_0 \cos \varphi_0}{n_1 \cos \varphi_1 + n_0 \cos \varphi_0}. \end{aligned} \quad (29.49)$$

Clearly these coefficients reduce to

$$r = \frac{n_1 - n_0}{n_1 + n_0}, \quad t = \frac{2n_0}{n_1 + n_0} \quad (29.50)$$

for the case of normal incidence where all the cosine terms become unity. There is no difference in this case between the coefficients for the p and s components. An expression for the energy reflectance at the interface R can be obtained by evaluating rr^* , where r^* is the complex conjugate of r . For nonabsorbing films r is real and this reduces to r^2 , and gives for normal incidence

$$R = \left(\frac{n_1 - n_0}{n_1 + n_0} \right)^2. \quad (29.51)$$

A similar expression for the energy transmittance T at the boundary can also be derived from t , but in this case the incident and transmitted beams are in different media, and the expression is not simply r^2 , but includes the ratio n_1/n_0 . Full details are given elsewhere [29.18, 138].

We consider now the slightly more complex situation of a thin film of thickness d_1 and refractive index n_1 deposited on a substrate of refractive index n_2 . In this case the value of n_0 for the incident medium will usually be the free-space value of unity. There will be multiple reflections as shown in Fig. 29.19b. It is clear that the total amplitude of the reflected beam is given by summing the amplitudes of the individual reflections into the incident medium, while the total amplitude of the transmitted beam is obtained by summing the amplitudes of the transmitted components into the substrate.

In traversing the film of thickness d_1 , the radiation undergoes a change in phase, which is accounted for by a *phase thickness* δ_1 , given by

$$\delta_1 = \frac{2\pi}{\lambda} n_1 d_1 \cos \varphi_1, \quad (29.52)$$

where λ is the wavelength in vacuum. In each case the summations lead to infinite series. These involve $\exp(-i2\delta_1)$ for reflection, where the beam traverses the film an even number of times, and $\exp(-i\delta_1)$ for transmission, where the beam traverses an odd number of times. The results of these summations give the amplitude reflectance R and transmittance T , respectively, as

$$R = \frac{r_1 + r_2 \exp(-2i\delta_1)}{1 + r_1 r_2 \exp(-2i\delta_1)} \quad (29.53)$$

and

$$T = \frac{t_1 t_2 \exp(-i\delta_1)}{1 + r_1 r_2 \exp(-2i\delta_1)} \quad (29.54)$$

In this case r_1 and t_1 represent the Fresnel coefficients between n_0 and n_1 , and r_2 and t_2 the coefficients between the media n_1 and n_2 . Depending on whether we are considering parallel or perpendicular polarisation (p or s) the relevant Fresnel coefficients from (29.48) and (29.49) should be used in these expressions. Equation (29.53) and (29.54) refer to the ratios of the *amplitudes* of the reflected and transmitted beams to that of the incident beam. In terms of the beam *energies*, the reflectance R and the transmittance T may be defined as the ratios of the reflected and transmitted beam energies to that of the incident energy. The energies of the reflected and transmitted beams are given by $n_0 R R^*$ and $n_2 T T^*$ respectively, where R^* and T^* represent the complex conjugates of R and T . We then obtain

$$R = \frac{n_0}{n_0} R R^* = \frac{r_1^2 + r_2^2 + 2r_1 r_2 \cos 2\delta_1}{1 + r_1^2 r_2^2 + 2r_1 r_2 \cos 2\delta_1} \quad (29.55)$$

for the reflectance, and

$$T = \frac{n_2}{n_0} T T^* = \frac{n_2}{n_0} \frac{t_1^2 t_2^2}{(1 + 2r_1 r_2 \cos 2\delta_1 + r_1^2 r_2^2)} \quad (29.56)$$

for the transmittance. Although these latter two expressions are reasonably compact, when the four Fresnel coefficients are substituted they become somewhat unwieldy. However, for the important case of normal incidence, where (29.50) applies, and where (29.52) simplifies to $\delta_1 = (2\pi/\lambda)n_1 d_1$, they reduce to still fairly

long expressions, but involving only the three refractive indices and δ_1 , i. e.

$$R = \frac{(n_0^2 + n_1^2)(n_1^2 + n_2^2) - 4n_0n_1^2n_2 + (n_0^2 - n_1^2)(n_1^2 - n_2^2) \cos 2\delta_1}{((n_0^2 + n_1^2)(n_1^2 + n_2^2) + 4n_0n_1^2n_2 + (n_0^2 - n_1^2)(n_1^2 - n_2^2) \cos 2\delta_1)} \quad (29.57)$$

and

$$T = 8n_0n_1^2n_2 / [(n_0^2 + n_1^2)(n_1^2 + n_2^2) + 4n_0n_1^2n_2 + (n_0^2 - n_1^2)(n_1^2 - n_2^2) \cos 2\delta_1] \quad (29.58)$$

The variations of R and T with δ_1 are shown in Fig. 29.20 [29.139] for normal incidence, where the refractive index of the incident medium $n_0 = 1$ and that of the substrate $n_2 = 1.5$. These correspond to air and glass respectively. Similar plots of these variations as a function of optical thickness n_1d_1 expressed as multiples of the wavelength λ are also common in the literature [29.1, 16, 138], where an optical thickness of unity corresponds to $\delta_1 = 2\pi$. The figure shows curves for three values of the film refractive index of 2.00, 1.70 and 1.23. For the first two of these $n_0 < n_1 > n_2$ and maxima in reflectance occur at $\pi/2$ and $3\pi/2$ with minima at $0, \pi$ and 2π , while for the third $n_0 < n_1 < n_2$ and the positions of the maxima and minima are reversed. In general the maximum and minimum reflectance values R_{\max} and R_{\min} , depend on the relative values of n_0, n_1 and n_2 . For the film index greater or less than those at both its boundaries, i. e. $n_0 < n_1 > n_2$ or $n_0 > n_1 < n_2$, we obtain

$$R_{\max} = \left(\frac{n_1^2 - n_0n_2}{n_1^2 + n_0n_2} \right)^2, \quad R_{\min} = \left(\frac{n_2 - n_0}{n_2 + n_0} \right)^2 \quad (29.59)$$

with maxima occurring when δ_1 is an odd multiple of $\pi/2$ (optical thickness n_1d_1 an odd number of quarter-wavelengths) and minima when δ_1 is an even multiple of $\pi/2$ (n_1d_1 an even number of quarter wavelengths). For the film index intermediate between those at its boundaries, i. e. $n_0 < n_1 < n_2$ or $n_0 > n_1 > n_2$ these results are reversed, and we obtain

$$R_{\max} = \left(\frac{n_2 - n_0}{n_2 + n_0} \right)^2, \quad R_{\min} = \left(\frac{n_1^2 - n_0n_2}{n_1^2 + n_0n_2} \right)^2 \quad (29.60)$$

Fig. 29.20 Variation of the energy reflectance R and transmittance T with phase thickness δ_1 for a nonabsorbing film at normal incidence for various film indices n_1 , with $n_0 = 1$ and $n_2 = 1.5$. The wavenumber σ is the reciprocal of the wavelength in vacuum λ . After [29.139] with permission from Elsevier Science

with maxima occurring when δ_1 is an even multiple of $\pi/2$, and minima at odd multiples (or maxima for n_1d_1 an even number of quarter wavelengths and minima an odd number). Equation (29.60) predicts that zero reflectance occurs when $n_1 = \sqrt{n_0n_2}$, and for the refractive index values of Fig. 29.20 give $n_1 = 1.23$. Thus a simple *anti-reflection coating* can be made by using a film of this index with optical thickness $\lambda/4$. This is clearly evident from the figure at the points where δ_1 has values of $\pi/2$ and $3\pi/2$. Another point which emerges from the figure is that if the refractive index of the film is the same as that of the glass, the system behaves as if the glass is uncoated. This situation is shown by the dotted line in the figure. Here the reflectance is 4%, exactly as predicted by (29.51) for an uncoated substrate (i. e. $n_0 = 1$ and $n_1 = 1.5$).

If the electromagnetic light wave is attenuated by a film layer, that layer is said to be *absorbing*, in contrast to the *transparent* layers considered previously. Providing the incident light beam is incident *normally* on the surface of the absorbing medium, the theory described above may be applied, with the proviso that the refractive index n is replaced by a *complex refractive index* $\mathbf{n} = n - ik$. The quantity k is called the *extinction coefficient*, and characterises absorption of energy within the film. Substitution of the complex refractive index in the appropriate expressions for the Fresnel coefficient

of (29.50), and in the expression for the phase thickness of (29.52) at normal incidence allows the amplitude reflectance R to be obtained. The energy reflectance R can be obtained by substituting the complex expressions for r and δ directly into (29.53) and evaluating RR^* . For more than two or three layers the results become intensely unwieldy, and matrix methods as mentioned below are considerably more useful. A simple example of the use of the complex refractive index will suffice. If we take the case of an incident beam in a nonabsorbing medium such as air with refractive index n_0 , incident upon an absorbing medium with complex refractive index $n_1 = n_1 - ik_1$, the amplitude reflectance can be determined by replacing n_1 by $n_1 - ik_1$ in (29.50) and evaluating rr^* . In this case the energy reflectance at the boundary becomes

$$R = \frac{(n_0 - n_1)^2 + k_1^2}{(n_0 + n_1)^2 + k_1^2} \quad (29.61)$$

in contrast to the result of (29.51) for a nonabsorbing medium.

In general, in absorbing films, the planes of constant phase are not parallel to the planes of constant amplitude for the electromagnetic wave disturbances. Only for the special case of normal incidence is this true, and thus in absorbing films it is usual to consider normal incidence only. The general case of oblique incidence is discussed in the standard texts on the optics of thin films [29.137, 138]. The behaviour of the energy reflectance and transmittance depend on the optical constants n and k . We have seen that in transparent films, R and T oscillate with the film thickness due to interference effects. In absorbing films with small k values, the oscillatory behaviour remains, but the amplitudes of the maxima decrease with increasing films thickness. For higher absorption values, particularly in the case of metals, intensity maxima are not observed, and an exponential decrease in transmittance with film thickness is seen.

Of particular use in the case of thin film stacks containing several layers is the matrix formalism, which allows the reflection and transmission properties to be determined. A 2×2 matrix characterises each layer of the stack, and allows the electric and magnetic field strengths to be expressed in terms of those of the adjacent layer. For transparent films this is given for the r -th layer in the form [29.140]

$$M_r = \begin{pmatrix} \cos \delta_r & i \sin \delta_r / n_r \\ i n_r \sin \delta_r & \cos \delta_r \end{pmatrix}, \quad (29.62)$$

where δ_r is the phase thickness and n_r is the refractive index of the r -th layer. The electric and magnetic field intensities in the adjacent $(r-1)$ -th layer, E_{r-1} and H_{r-1} , are related to those in the r -th layer E_r and H_r by

$$\begin{pmatrix} E_{r-1} \\ H_{r-1} \end{pmatrix} = M_r \begin{pmatrix} E_r \\ H_r \end{pmatrix}. \quad (29.63)$$

Repeated application of (29.63) to a stack of layers enables E_0 and H_0 in the incident medium (n_0) to be expressed in terms of the field intensities in any other layer of the stack. Knowing the n values for each of the various layers of the stack, a *characteristic matrix* (also 2×2) for the entire stack is obtained by repeated matrix multiplication of the individual layer matrices, and allows E_0 and H_0 to be obtained in terms of the transmitted field intensities at the opposite side of the stack. The energy reflectance is then easily obtained. Similar matrices to those in (29.62) may also be defined for the case of absorbing films, although it is then usual to work in terms of the layer admittance η , defined as the ratio of the transverse components of the magnetic to the electric vectors [29.138].

A relatively simple example of an interesting system is a stack of layers of equal optical thickness, but with alternating high (H) and low (L) refractive indices [29.140]. If the optical thicknesses correspond to $\lambda/4$ (a quarter-wave stack), there is a highly reflective region at the wavelength λ , with other highly reflecting regions at 2λ , 3λ , etc. The reflectance value becomes higher the more layers there are in the stack, and approaches unity for a few layers. If the refractive index of the incident medium is n_0 , that of the substrate n_S , and those of the high- and low-index regions n_H and n_L , respectively, the energy reflectance for an even number of layers $2s$ (n_L next to substrate) is given by

$$R_{2s} = \left(\frac{n_S f - n_0}{n_S f + n_0} \right)^2 \quad (29.64)$$

where $f = (n_H/n_L)^{2s}$. For an odd number of layers ($2s+1$), with n_H next to the substrate, the energy reflectance becomes

$$R_{2s+1} = \left(\frac{n_H^2 f - n_0 n_S}{n_H^2 f + n_0 n_S} \right)^2. \quad (29.65)$$

The bandwidth of the highly reflecting region depends on $\sin^{-1}[(n_L - n_H)/(n_L + n_H)]$, and thus is limited by the refractive indices available. Bandwidth can be increased by using a stack with layer thicknesses increasing in geometrical progression.

In addition to antireflection and highly reflecting coatings, various types of optical filters can be designed. Perhaps the simplest is the Fabry–Perot interference filter, which consists of two highly reflecting stacks, separated by a layer of optical thickness $\lambda/2$. This results in a very narrow transmission band at wavelength λ , with a rejection region on either side. Filter designs are usually based on computer evaluations of the optical matrices. These include band-pass, band-stop and edge filters. These are well beyond the scope of the present article and the reader is referred to the literature [29.30, 138, 141, 142].

In this section some of the basic optical properties have been described, with the primary emphasis on non-absorbing films at normal incidence. Several interesting film arrangements have been described, again for non-absorbing films. Implicit to any system there is some absorption, but this can be accounted for if both the optical constants are known. Usually the design process involves the manipulation of several layer matrices, but this is handled effectively by modern computer technology. The optical properties of highly absorbing films are described by *Abelès* [29.143], who also considers inhomogeneous films. Other useful references on the theory and detailed optical properties of various aspects of thin films may be found in the literature: theory and calculations [29.144], antireflection coatings [29.145], filters [29.142, 146, 147] and mirrors [29.148].

29.3.2 Electrical Properties

The electrical properties of thin films are one of their most important physical features, and differ from those of the corresponding bulk material for various reasons. Electrical properties cover a particularly wide field, and in this section only two important examples are covered. The first of these is the lateral conductivity (or corresponding resistivity) of thin metallic films. In metals we are usually concerned only with one type of charge carrier, electrons, and thus variations in conductivity σ due to the presence of both carrier types (such as compensation effects) are not considered. The main cause of deviations from the bulk material conductivity values is curtailment of the bulk electron mean free path λ_0 by the dimensions of the film. Clearly, if the film thickness $d < \lambda_0$, many instances of electron scattering occur at the film surfaces, thus reducing the effective electron mean free path and decreasing the conductivity. Modern theories also take into account electron scattering by individual grain boundaries as well as by the film surfaces. The second example of electrical properties in thin films

is that of high-field conduction in insulators and semiconductors. Electric fields in thin films may approach the dielectric breakdown strength, and under these conditions the usual ohmic behaviour is not followed, but a range of different limiting conduction processes may take place. Conduction in semiconductors at somewhat lower electric fields is not discussed here, but is covered in detail elsewhere in the literature [29.1, 15, 18, 149]. Semiconductor conductivity is a broad subject, underlying the operation of many different electronic devices. We might note that the conductivity of semiconductors in their surface regions (and therefore also in semiconductor thin films) differs from that of the bulk material owing to depletion or accumulation regions at the surfaces, and that the application of a surface electric field forms the basis of several semiconductor devices, such as metal–oxide–semiconductor (MOS) transistors. Furthermore, the mobility of carriers in semiconductors frequently follows similar variations to those of the conductivity in metallic films, for essentially the same regions, in that the surface and/or grain boundary scattering significantly influence the mobility and thus the conductivity.

Electrical conductivity in metallic films

The electrical conductivity in bulk metals σ_0 is given generally by an expression of the form

$$\sigma_0 = \frac{ne^2\lambda_0}{mv}, \quad (29.66)$$

where n is the concentration of free electrons, e is the electronic charge, λ_0 the bulk electron mean free path, m the electron effective mass and v the electron Fermi velocity. This expression results from the free-electron gas theory of metals, derived from the work of Drude, Lorentz and Sommerfeld. The main feature of this result is that the electrical conductivity is proportional to the mean free path, and that if the mean free path is curtailed by any means, then the conductivity will be reduced, all other considerations remaining unaltered. A further consideration is the well-known result termed Matthiessen's rule,

$$\rho_0 = \rho_d + \rho_{ph}(T), \quad (29.67)$$

where the bulk resistivity $\rho_0 (= 1/\sigma_0)$ is given by the sum of contributions from static defects and impurities ρ_d and from phonons $\rho_{ph}(T)$. The latter contribution effectively isolates the main temperature-dependent effect from other scattering mechanisms, unless they too are temperature-dependent. Temperature-dependent

phonon interactions increase with increasing temperature, giving rise to the positive temperature coefficient of resistivity (TCR) in metals. At very low temperatures $\rho_{\text{ph}}(T) \rightarrow 0$, and only the residual resistivity ρ_d remains. For the case of a thin metal film, scattering at the surfaces also comes into play, and Matthiessen's rule is modified by the addition of an extra surface-scattering resistivity term ρ_s to give

$$\rho_f = \rho_d + \rho_{\text{ph}}(T) + \rho_s \quad (29.68)$$

for the thin-film resistivity ρ_f . For very thick films $\rho_s \approx 0$, since the mean free path is not then limited by the surfaces, and the film resistivity is effectively the same as the bulk value. When ρ_s is significant for thinner films, $\rho_f > \rho_0$, and the film conductivity $\sigma_f < \sigma_0$. The above discussions follow naturally from the treatise in Chapt. 2.

Over a century ago, Thomson [29.151] was the first to suggest that observed decreases in the conductivity of thin films as compared to the bulk values are the result of the limitation of the electron mean free path by the specimen size. He made the following assumption in obtaining an expression for the film conductivity: the bulk mean free path in the metal is a constant λ_0 , greater than the film thickness d , and that when electrons collide with the internal film surfaces the scattering is independent of the angle at which they strike, i.e. the scattering is diffuse. Collisions occurring in the film were split into two regions, in the first the mean free path is determined by the surfaces (top and bottom) and in the second the mean free path is not limited by scattering at the surfaces. In terms of the parameter

$$k = \frac{d}{\lambda_0}, \quad (29.69)$$

the ratio of the film thickness to the bulk mean free path, the ratio of the film to bulk conductivity was determined as

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} = \frac{k}{2} \left[\ln\left(\frac{1}{k}\right) + \frac{3}{2} \right]. \quad (29.70)$$

Fuchs [29.150] pointed out that this derivation neglected mean free paths starting at the film surfaces, and also the statistical distribution of the mean free paths about λ_0 in the bulk metal. A corrected version of Thomson's model for very thin films, i.e. $d \ll \lambda_0$ ($k \ll 1$), where effectively all the mean free paths start from one of the surfaces, yields an alternative result [29.152]

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} = k \left[\ln\left(\frac{1}{k}\right) + 1 \right]. \quad (29.71)$$

Although both expressions predict a decrease in conductivity below the bulk value for films, neither gives a sensible prediction for very thick films, i.e. $d \gg \lambda_0$ ($k \gg 1$).

A more useful general model to account for variations of conductivity with film thickness was introduced by Fuchs [29.150], who formulated the problem in terms of the Boltzmann transport equation, which describes the way in which the electron energy changes due to applied fields and collisions. Readers are referred to the original paper, or to one of the reviews mentioned at the end of this section, for details of the mathematical arguments. The final result of this model is

$$\begin{aligned} \frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} = 1 + \frac{3}{4} \left(k - \frac{k^3}{12} \right) B(k) \\ - \frac{3}{8k} (1 - e^{-k}) - \left(\frac{5}{8} + \frac{k}{16} + \frac{k^2}{16} \right) e^{-k}, \end{aligned} \quad (29.72)$$

where $B(k)$ is a representative of the set of exponential integral functions, given by

$$B(x) = -\text{Ei}(-x) = \int_x^\infty \frac{e^{-y}}{y} dy. \quad (29.73)$$

Fig. 29.21 Dependence of the ratio of film to bulk resistivity ρ_f/ρ_0 on the ratio of film thickness to bulk mean free path $k = d/\lambda_0$ predicted by the model of Fuchs [29.150]; p is the specularity parameter, with $p = 0$ representing totally diffuse scattering and $p = 1$ representing totally specular scattering, where for the latter $\rho_f/\rho_0 = 1$. The curve labelled $p = 0.5$ is intermediate between these two values

Figure 29.21 shows the dependence of ρ_f/ρ_0 ($=\sigma_0/\sigma_f$) on k over the range 0.1–10 for the curve labelled $p = 0$ (diffuse scattering). Here it is clear that the resistivity drops to the bulk value for thick films. Various approximations for (29.72) are frequently quoted to aid computation in specific thickness ranges. For thick films ($k \gg 1$)

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx 1 - \frac{3}{8k}. \quad (29.74)$$

This clearly shows that as $k \rightarrow \infty$, $\sigma_f \rightarrow \sigma_0$. For thinner films ($k \ll 1$), Campbell [29.153] quotes

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4} \left[\ln\left(\frac{1}{k}\right) + 0.4228 \right] \quad (29.75)$$

and for very thin films Sondheimer [29.154] gives

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4} \left[\ln\left(\frac{1}{k}\right) \right]. \quad (29.76)$$

Equations (29.70), (29.71), (29.75) and (29.76) give some confidence in the general approach, since they are all of comparable form, with the right-hand sides each consisting of a constant $\times k \times [\ln(1/k) + \text{another constant}]$.

Fuchs also considered the case where the electron scattering at the surfaces was not totally randomised, and that a constant proportion of electrons p are scattered specularly. p is termed the *specularity parameter*, where $p = 0$ for the case of totally diffuse scattering and $p = 1$ for totally specular scattering. Clearly in the latter case the film surfaces do not affect the conductivity, and σ_f reduces to the bulk value. Figure 29.21 also shows the variation of ρ_f/ρ_0 for $p = 0.5$ (intermediate between diffuse and specular scattering) and $p = 1$ (totally specular scattering). Again for the case of some specular scattering there are limiting expressions for thick films ($k \gg 1$) and thin films ($k \ll 1$), given respectively by

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx 1 - \frac{3(1-p)}{8k} \quad (29.77)$$

and

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4} (1+2p) \left[\ln\left(\frac{1}{k}\right) + 0.4228 \right], \quad (29.78)$$

where p is small in (29.78). For totally diffuse scattering, where $p = 0$, these two expressions reduce to the previous results of (29.74) and (29.75). An alternative expression for thin films is also given by Sondheimer [29.154],

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4} \left(\frac{1+p}{1-p} \right) \ln\left(\frac{1}{k}\right). \quad (29.79)$$

This reduces to (29.76) for $p = 0$, and for small k and p is consistent with (29.78).

Both Lucas [29.155] and Juretschke [29.156, 157] have extended the specularity analysis by assuming a different specularity parameter for each side of the film, i. e. p and q . This is of course quite reasonable, in that the specularity parameter of the lower (substrate) surface is likely to be heavily influenced by the substrate surface. The thick- ($k \gg 1$) and thin-film ($k \ll 1$) approximations in this case are then

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx 1 - \frac{3}{8k} \left[1 - \left(\frac{p+q}{2} \right) \right] \quad (29.80)$$

and

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} \approx \frac{3k}{4} \frac{(1+p)(1+q)}{(1-pq)} \ln\left(\frac{1}{k}\right), \quad (29.81)$$

respectively. For identical surfaces with $p = q$, these expressions reduce to (29.77) and (29.79) respectively. Tabulated values of ρ_f/ρ_0 are given by Chopra [29.18] as functions of k for various combinations of p and q . The whole topic of the size-dependent electrical conductivity in thin metallic films and wires is thoroughly reviewed by Larson [29.158], but omitting the important work on grain-boundary scattering of Mayadas and Shatzkes [29.159]. This is, however, covered in a more recent book reviewing size effects in thin films generally [29.160], which also includes useful tabulated conductivity data.

As mentioned above, an important development in size-effect models came about with the inclusion of grain-boundary scattering [29.159]. In a bulk sample, the individual grains are normally considerably larger than the bulk mean free path λ_0 , and do not therefore affect the conductivity. However, in thin films, the grain sizes and orientations depend on the preparation method and conditions. Typical grain sizes are of the same order as λ_0 and therefore scattering at their boundaries will influence the conductivity. Mathematically, the model takes account of the fact that grains tend to grow in a columnar structure, with the axes normal to the film plane. Single grains usually extend between both film surfaces, and thus their upper and lower boundaries do not affect the conductivity. Mayadas and Shatzkes argue that only grain boundaries normal to the film plane influence the conductivity. The grain boundaries are represented by δ -function potentials, and are used in the model in the solution of the Boltzmann transport equation, subject to suitable boundary conditions. The model is developed in terms of a dimensionless parameter α , given by

$$\alpha = \frac{\lambda_0}{D} \frac{R}{1-R}, \quad (29.82)$$

where, as before λ_0 is the bulk mean free path, D is the mean grain dimension, and R is the grain-boundary electron reflection coefficient. The ratio of the grain-boundary conductivity σ_g (and the corresponding resistivity ρ_g) to the bulk values are then given by

$$\frac{\sigma_g}{\sigma_0} = \frac{\rho_0}{\rho_g} = 3 \left[\frac{1}{3} - \frac{1}{2}\alpha + \alpha^2 - \alpha^3 \ln \left(1 + \frac{1}{\alpha} \right) \right]. \quad (29.83)$$

This is easy to evaluate, and the dependence of ρ_g/ρ_0 ($= \sigma_0/\sigma_g$) on α is shown in Fig. 29.22. For small values of α (i. e. large grain size D , small bulk mean free path λ_0 , or small reflection coefficient R) the grain boundaries do not affect the overall conductivity, which remains at the bulk value. However, for large α the grain-boundary resistivity increases (conductivity decreases). For very large ($\alpha \gg 1$) and very small ($\alpha \ll 1$) values of α , (29.83) has the limiting approximations

$$\frac{\sigma_0}{\sigma_g} = \frac{\rho_g}{\rho_0} \approx \frac{4}{3}\alpha \quad (29.84)$$

and

$$\frac{\sigma_0}{\sigma_g} = \frac{\rho_g}{\rho_0} \approx 1 + \frac{3}{2}\alpha, \quad (29.85)$$

respectively. Note that following the original work [29.159] the latter two expressions are quoted as the ratio ρ_g/ρ_0 ($= \sigma_0/\sigma_g$), i. e. the reciprocal of the ratio in (29.83).

Fig. 29.22 Dependence of the ratio of grain-boundary to bulk resistivity ρ_g/ρ_0 on the parameter α from the model of Mayadas and Shatzkes [29.159]. The data are calculated from (29.83)

Mayadas and Shatzkes [29.159] also considered the case of grain-boundary scattering in conjunction with scattering at the film surfaces, and followed the Fuchs [29.150] formulation to arrive at an expression for the overall film resistivity ρ_f . Unfortunately, the resulting expression could not be evaluated analytically, requiring numerical solution. Detailed comparisons between the basic Fuchs model with $p = 0$ and $p = 0.5$, and their model using the same values of p and including grain-boundary scattering with $\alpha = 1$, led these workers to interpret their results as showing an enhancement of the intrinsic resistivity ρ_g in polycrystalline samples in which grain size is constant and independent of film thickness. However, discrepancies between the Fuchs and Mayadas–Shatzkes models become most apparent for very large α (very small grain size, D). For this situation the deviation corresponds to the additional resistivity arising from grain boundaries rather than from surface scattering [29.161, 162]. Useful tabulated data of resistivity ratios in samples with both grain-boundary and surface scattering are given elsewhere in the literature [29.160, 163].

Finally, we briefly discuss the thickness variations of the temperature coefficient of resistivity. This is a measure of the response of the resistivity to changes in temperature, and is usually denoted by the symbol α . To avoid confusion with the Mayadas–Shatzkes parameter, here we denote it by α_T . The temperature coefficient of resistivity is given for the bulk (α_{T0}) and for thin films (α_{Tf}) by

$$\alpha_{T0} = \frac{1}{\rho_0} \frac{d\rho_0}{dT}; \quad \alpha_{Tf} = \frac{1}{\rho_f} \frac{d\rho_f}{dT} \quad (29.86)$$

where ρ_0 and ρ_f are the bulk and thin-film resistivities, as given in (29.67) and (29.68). From the above relationships, and Matthiesen's rule, it is possible to derive expressions for α_{Tf}/α_{T0} in a similar manner as ρ_f/ρ_0 . Referring to (29.68), ρ_d is essentially temperature-independent, while the temperature dependence of ρ_s depends on the film thickness. For thicker films ($k \gg 1$), ρ_s is also temperature-independent, and thus

$$\frac{d\rho_f}{dT} = \frac{d\rho_{ph}}{dT} \quad (29.87)$$

Similarly, from (29.67) for the bulk material

$$\frac{d\rho_0}{dT} = \frac{d\rho_{ph}}{dT} \quad (29.88)$$

and therefore both the differentials in (29.86) are equal, and we obtain

$$\alpha_{T0}\rho_0 = \alpha_{Tf}\rho_f. \quad (29.89)$$

This useful result implies that

$$\frac{\sigma_f}{\sigma_0} = \frac{\rho_0}{\rho_f} = \frac{\alpha_{Tf}}{\alpha_{T0}} \quad (29.90)$$

and that for the case of thicker films the ratio of the film-to-bulk temperature coefficient of resistivity is equal to the ratio of film-to-bulk conductivity. For the case of thinner films ($k \ll 1$), the situation is complicated by the fact that ρ_s is also temperature-dependent, because the mean free path decreases with increasing temperature and becomes significant for small k . Various calculated data for α_{Tf} are given elsewhere in the literature [29.6, 18, 153, 158, 160], to which the reader is referred for a fuller discussion. Discussions concerning the applicability of the various models described above to several types of metallic film are also given in some of these references, and a wider coverage including additional contributions to the size effect models, which cannot be included in the present work, is given in the book by *Tellier and Tosser* [29.160].

High-field conduction in insulating and semiconducting thin films

Here electrical conductivity is considered for the case where a voltage is applied across an insulating or semiconducting thin film prepared in a sandwich configuration between metallic electrodes. This situation is in direct contrast to that described in the previous section, in that the intrinsic film conductivity is significantly lower, and the electric field applied can be extremely high, even when only low voltages are applied. The latter point is clearly illustrated by the fact that in a film of thickness $1 \mu\text{m}$ subjected to a voltage of only 10 V, the mean electric field established across the film is 10^7 V/m , approaching the dielectric breakdown strength of many materials. Several high-field conduction mechanisms that may in principle occur in thin dielectric films have been thoroughly reviewed in the literature [29.164]. These have also been observed in relatively wide-band-gap semiconducting films. These processes are discussed later in this section, together with the appropriate current density–voltage expressions which aid in their identification and analysis. First, however, it is useful to discuss the types of electrical contact which may be applied to dielectric films, since the dominant conduction process is frequently determined by the type of electrical contact and its interfacial properties.

Simmons [29.164] has demonstrated that the type of electrode used significantly influences the conduction processes which may be observed; the various conduction mechanisms were classified as either *bulk-limited*

or *electrode-limited*. For the former the charge carriers are generated in the bulk of the material and the electrodes merely serve to apply a potential which generates a drift current. In the latter, at the interface between the electrode and the insulator or semiconductor, a potential barrier to the flow of charge is established, which limits the current. Contacts themselves are said to be either *ohmic* or *blocking*, with an intermediate *neutral* contact. Blocking contacts are conventionally known as Schottky barriers. In principle, the type of contact formed depends on the relative work functions of the insulator or semiconductor ψ_i and that of the metal contact ψ_m . Excellent energy-band diagrams of the various types of contact are given in the literature [29.164], and are reproduced elsewhere in descriptions of contacts to cadmium compound films [29.38] and to nanostructures [29.11]. In equilibrium the vacuum and the Fermi levels are continuous across the interface, and with no applied voltage the Fermi level also must be flat, in order that no current flows. Away from the interface in the bulk of the material, the energy difference between the vacuum and Fermi levels will be equal to the work function ψ_i , and it can easily be seen that the potential barrier height at the interface φ_0 is given by

$$\varphi_0 = \psi_m - \chi, \quad (29.91)$$

where χ is the film electron affinity and ψ_m is the metal work function. However, it is the *type* of contact rather than its precise barrier height which determines the type of conductivity observed. We consider primarily electrons as the charge carriers, as it has been argued that for insulators conduction by holes may normally be ignored, owing to relatively low mobilities and to immobilisation by trapping effects. Similar arguments are also applicable in the case of wide-band-gap semiconductors, and thus for both insulators and some semiconductors n-type conductivity is usual. For p-type conductivity, the conditions concerning the relative values of the work functions are reversed [29.165].

Ohmic contacts occur for electron injection when $\psi_m < \psi_i$. Electrons are injected from the electrode into the insulator or semiconductor in order to comply with thermal equilibrium requirements. They are subsequently located within the insulator or semiconductor conduction band and penetrate a distance λ_0 below the interface, forming a region of negative space charge which is termed an *accumulation region*. Upwards band bending of the conduction band occurs in the accumulation region, beyond which the dielectric is shielded from the electrode. The accumulation region acts as a charge reservoir, and can supply electrons to the

material as required by the bias conditions. It has been pointed out by *Simmons* [29.164] that the conductivity is limited by the rate at which electrons can flow into the bulk of the material, and is therefore bulk-limited. Conversely, blocking contacts or Schottky barriers occur when $\psi_m > \psi_i$. In this case the initial flow of charge is reversed, with electrons flowing from the insulator or semiconductor to the metal electrode. In contrast to the case for ohmic contacts, this results in a positive space-charge region near the interface in the insulator or semiconductor, which, owing to the absence of electrons, is termed a *depletion region*. An equal and opposite negative charge is induced on the electrode, and the interaction between the two charges establishes a local electric field near the interface. In this case the conduction band in the insulator or semiconductor bends downwards, and the free-electron concentration in the interfacial region is much lower than in the bulk of the film material. The rate of flow of electrons is thus limited by the rate at which they can flow over the interfacial barrier, and the conductivity is electrode-limited.

Although, in principle, the type of contact established depends on the relative values of ψ_m and ψ_i , in reality such considerations are usually inadequate in predicting the type of contact formed, because of the existence of *surface states*. These are due either to the effects of unsaturated bonds and impurities at the interface [29.166] or to the departure from periodicity in the structure at the interface. It is very difficult to accurately predict a priori the presence and concentration of surface states. If a significant concentration of surface states does exist, (29.91) is inapplicable and the type of contact and the conduction process are determined almost entirely by their presence.

In the remainder of this section the bulk-limited conduction processes are first considered, where the conductivity does not depend on the barrier height at the interface. Following this the electrode-limited processes are considered, where the barrier height becomes a significant feature in the current density–voltage (J – V) equations.

A particularly important conduction process in insulating and semiconducting thin films is that of space-charge-limited conductivity (SCLC). For SCLC to occur there is a requirement that the injecting electrode is an ohmic contact. Thus there is a charge reservoir available in the accumulation region, and electrons do not need to be excited over a potential barrier. At low voltages the thermally generated carrier concentration exceeds the injected concentration, and the current density J is proportional to the applied voltage V , following Ohm's

law,

$$J = n_0 e \mu \frac{V}{d}, \quad (29.92)$$

where n_0 is the thermally generated carrier concentration (electrons), e is the electronic charge, μ the mobility and d the film thickness. When the injected electron concentration exceeds that of the thermally generated concentration the SCLC current becomes dominant. SCLC current density–voltage relationships are derived by taking into account both the drift and diffusion currents, and solving Poisson's equation. This results in an expression for the electric field as a function of distance from the interface. Charge-carrier traps normally exist within the insulating or semiconducting film, and these are effective in mopping up or immobilising most of the injected electrons. For shallow traps located at a discrete energy E_t below the conduction band edge the SCLC current density is given by [29.164]

$$J = \frac{9}{8} \varepsilon_r \varepsilon_0 \theta \mu \frac{V^2}{d^3}, \quad (29.93)$$

where ε_r is the relative permittivity of the material, ε_0 the permittivity of free space and θ is the ratio of free to trapped charge. This expression predicts that $J \propto V^2$ and $J \propto d^{-3}$, and the search for these relationships is an important tool in identifying SCLC dominated by a discrete trap level. For perfect materials which do not contain traps, θ is replaced by unity in (29.93). The ratio of free to trapped charge is given by [29.167]

$$\theta = \frac{N_c}{N_{t(s)}} \exp\left(-\frac{E_t}{k_B T}\right), \quad (29.94)$$

where N_c is the effective density of states at the conduction band edge, $N_{t(s)}$ is the shallow trap concentration located at the discrete energy level, k_B is Boltzmann's constant and T is the absolute temperature. A transition between ohmic conductivity and SCLC takes place when the injected carrier concentration first exceeds the thermally generated carrier concentration. An expression for the transition voltage V_t at which this occurs is obtained by simultaneously solving (29.92) and (29.93) to yield

$$V_t = \frac{8en_0d^2}{9\theta\varepsilon_r\varepsilon_0}. \quad (29.95)$$

SCLC of this type, showing square-law J – V behaviour, has been observed in many types of thin films. In SbS_3 dielectric films, with bismuth oxide ohmic contacts, the current was at first ohmic, before a transition to SCLC [29.168]. Current density was also found to be

proportional to $1/d^3$ at constant voltage, and the transition voltage V_t showed the characteristic linear variation with d^2 . It has also been observed in CdS films [29.40, 169, 170], particularly with In injecting electrodes, and a discrete-trap concentration of $2.5 \times 10^{20} \text{ m}^{-3}$ was deduced [29.40]. In CdTe, a square-law SCLC behaviour was recorded in electro-deposited Ni–CdTe–Au structures [29.171]. The work also showed a systematic increase in current density with temperature over the range 273–338 K, together with the expected $J \propto 1/d^3$ behaviour. Dharmadhikari [29.172] observed similar behaviour in evaporated CdTe films in the lower voltage range, although power-law behaviour became apparent at higher voltages. CdSe films have also been reported as showing square-law SCLC [29.173, 174]. In organic films, the phthalocyanines are well known for exhibiting SCLC behaviour [29.111]. Square-law behaviour with discrete trap levels has been seen in several of these materials, with typical activation energies of 0.77 eV [29.175] and 0.62 eV [29.176] in copper phthalocyanine, 0.42 eV in lead phthalocyanine [29.177], 0.58 eV in nickel phthalocyanine [29.178] and 0.45 eV and 0.69 eV in cobalt phthalocyanine [29.179]. These values appear to vary according to the central metal atomic species in the molecule, and also with the oxygen content. In general these materials are p-type, having a trap concentration for discrete levels in the range $5 \times 10^{16} - 7.1 \times 10^{25} \text{ m}^{-3}$.

For amorphous and polycrystalline materials, where a single shallow trap level is unlikely to be present, several poorly defined trap levels can lead to an overall exponential distribution of traps $N(E)$ [29.167] given by

$$N(E) = N_0 \exp\left(-\frac{E}{k_B T_t}\right), \quad (29.96)$$

where $N(E)$ is the trap concentration per unit energy range at an energy E below the conduction band edge, N_0 is the value of $N(E)$ at the conduction band edge and $T_t > T$ is a temperature parameter which characterises the distribution. Furthermore, it can be shown that the total concentration of traps comprising the distribution $N_{t(e)}$ is [29.181]

$$N_{t(e)} = N_0 k_B T_t. \quad (29.97)$$

Lampert [29.182] obtained an expression for the current density by assuming an exponential trap distribution as described by (29.96) to yield

$$J = e\mu N_c \left(\frac{\varepsilon_r \varepsilon_0}{e N_0 k_B T_t}\right)^l \frac{V^{l+1}}{d^{2l+1}}. \quad (29.98)$$

This expression predicts a power-law dependence of J on V , with the exponent $n = l + 1$, where l represents the ratio T_t/T . J is also expected to be proportional to $d^{-(2l+1)}$. Similarly to the case for a single shallow trap level, there is also a transition voltage between ohmic conduction and SCLC dominated by an exponential trap distribution. The transition voltage in this case is given by [29.183]

$$V_t = \left(\frac{n_0}{N_c}\right)^{1/l} \frac{e N_0 k_B T_t d^2}{\varepsilon_r \varepsilon_0}. \quad (29.99)$$

Many instances of power-law SCLC are also reported in the literature. Zuleeg [29.169] observed a cubic power-law dependence at higher voltages in his CdS films, which suggested that an exponential trap distribution was present. Dharmadhikari [29.172] appears to have been the first to observe a power-law J – V dependence in CdTe films at higher voltage levels, in addition to the square-law dependence at lower voltages. Very high exponents were recorded, although at the time this was not analysed using the exponential trap distribution expressions given above. This connection was made in a later series of measurements [29.180], where the intermediate square-law behaviour was absent. This

Fig. 29.23a–c Room-temperature current density–voltage characteristics for evaporated Al–CdTe–Al sandwich structures of thickness 0.31 μm (a), 0.45 μm (b) and 0.56 μm (c), showing ohmic conduction and SCLC. U is the applied voltage. After [29.180] with permission from Wiley–VCH

J - V dependence is shown in Fig. 29.23 [29.180] for three different film thicknesses, and is typical of many results on various different materials showing an exponential trap distribution. Similar exponential trap distributions have also been identified in some CdSe films [29.184–186], notwithstanding the earlier results which indicated discrete trap levels [29.173, 174]. The differences between these two classes of results appear to depend on the different deposition conditions and processing used. Exponential trap distributions are extremely prevalent in phthalocyanine films, and were originally investigated by *Sussman* [29.187] for copper phthalocyanine films with ohmic Au electrodes. The material was shown to be p-type, and exhibited exponent values n in the J - V characteristics in the range 2.6–4.0. The predicted thickness dependence for this type of conductivity was also observed. Many other phthalocyanine films have subsequently shown this type of conductivity, and data on these are tabulated and compared in the literature [29.111]. Total trap concentrations for the exponential distributions are in the range 6×10^{20} – $9.3 \times 10^{26} \text{ m}^{-3}$.

Using the above Eqs. (29.96–29.98) as a starting point, it was shown by the present author [29.188] that for SCLC dominated by an exponential trap distribution, measurements of J as a function of temperature at constant applied voltage in the SCLC region are sufficient to determine both the mobility and the trap concentration. If the data are plotted in the form $\log_{10} J$ against $1/T$ the curves should be linear, and when extrapolated to negative values of $1/T$, should all intersect at a common point irrespective of the applied voltage. The coordinates of this point are given by

$$\log_{10} J = \log_{10} \left(\frac{e^2 \mu d N_c N_{t(e)}}{\varepsilon_r \varepsilon_0} \right); \quad \frac{1}{T} = -\frac{1}{T_t}. \quad (29.100)$$

Other useful results enabling data to be extracted from these plots are that for the gradient, given by

$$\frac{d(\log_{10} J)}{d(1/T)} = T_t \log_{10} \left(\frac{\varepsilon_r \varepsilon_0 V}{e d^2 N_{t(e)}} \right) \quad (29.101)$$

and for the intercept $\log_{10} J_0$ on the $\log_{10} J$ axis, which is

$$\log_{10} J_0 = \log_{10} \left(\frac{e \mu N_c V}{d} \right) \quad (29.102)$$

This set of equations has been used to determine mobility and trap concentration in several different materials showing this form of SCLC, including copper phthalocyanine, where these quantities were measured as

functions of the ratio of evaporation background pressure to deposition rate [29.189]. In another example the method was used to determine these quantities in semiconducting CdTe films [29.190].

We might mention that *Rose* [29.167] also explored the possibility of a uniform trap distribution, in addition to discrete energy levels and the exponential distribution. In this case $J \propto V \exp(tV)$, where t is a temperature-dependent constant, but this is observed far less frequently than the square-law and power-law behaviour described above. An example is in the case of electrodeposited p-type CdTe films [29.191], where *Rose's* expression was followed and the trap concentration per unit energy range was $10^{21} \text{ eV}^{-1} \text{ m}^{-3}$. It was also observed in early work on copper phthalocyanine films with ohmic Au electrodes [29.192]. The discussion above for all types of SCLC considers carrier injection of a single type only. Double injection, when one electrode is ohmic for electrons and the other ohmic for holes, is covered in detail in the text by *Lampert* and *Mark* [29.193] on current injection in solids, and is also discussed by *Lamb* [29.166].

The second bulk-limited conduction process to be discussed is the Poole–Frenkel effect, which is essentially the field-assisted lowering of the Coulombic potential barrier ϕ between electrons located at impurity sites and the edge of the conduction band. Electrons in such centres are unable to contribute to the conductivity until they overcome the potential barrier ϕ and are promoted into the conduction band. For an applied electric field F the potential is reduced by an amount eFx where e is the electronic charge and x is the distance from the centre. For high electric fields the lowering of the potential can be significant. Such a variation is illustrated in the literature, usually for the case of a donor level located an energy E_d below the bottom of the conduction band [29.164]. The potential energy of the electron in the Coulombic field is $-e^2/4\pi\varepsilon_r\varepsilon_0x$, and there is also another contribution to the potential energy, $-eFx$, resulting from the applied field F . The combined effect of both these contributions to the potential energy is that there is a maximum in the potential energy for emission at a distance x_m from the centre. The effective potential barrier for Poole–Frenkel emission is then lowered by an amount $\Delta\phi_{\text{PF}}$, which depends on the electric field according to the relationship

$$\Delta\phi_{\text{PF}} = \beta_{\text{PF}} F^{1/2}, \quad (29.103)$$

where

$$\beta_{\text{PF}} = \left(\frac{e^3}{\pi\varepsilon_r\varepsilon_0} \right)^{1/2} \quad (29.104)$$

is referred to as the Poole–Frenkel field-lowering coefficient. The conductivity, and consequently the current density, depend exponentially on the potential barrier for excitation of electrons into the conduction band, and since this is lowered by $\Delta\varphi_{\text{PF}} = \beta_{\text{PF}} F^{1/2}$ the current density is increased by an exponential factor. The current density is given by

$$J = J_0 \exp\left(\frac{\beta_{\text{PF}} F^{1/2}}{kT}\right), \quad (29.105)$$

where $J_0 = \sigma_0 F$ is the low-field current density. Although J_0 in this expression depends linearly on F , it is frequently ignored in comparison with the exponential term, which increases far more rapidly with F . Equation (29.105) is usually applicable for thin-film insulators and semiconductors in the presence of traps. If, rarely, traps are absent and the low-field conductivity σ_0 shows an intrinsic dependence proportional to the factor $\exp(-E_g/2kT)$, where E_g is the energy gap, then a factor of 2 appears in the denominator of the exponential term in (29.105) [29.164]. Since $F = V/d$, the above expression can be written

$$J = J_0 \exp\left(\frac{\beta_{\text{PF}} V^{1/2}}{kTd^{1/2}}\right). \quad (29.106)$$

Therefore a plot of $\log J$ against $V^{1/2}$ should show a linear relationship in the case of Poole–Frenkel conductivity, from which a value of the field-lowering coefficient can be deduced and compared with the theoretical value of (29.104). If it is necessary for the variation of the pre-exponential factor to also be taken into account, then a linear plot of $\log(J/V)$ against $V^{1/2}$ should be obtained.

Modifications to (29.105) have been proposed to account for the somewhat different current density dependence in the presence of various combinations of donors and traps. *Simmons* [29.164] mentioned the case where the material contains donor levels below the Fermi level as well as shallow neutral traps, in which the coefficient of $F^{1/2}/kT$ is one half of the theoretical value given by (29.104). For the case of a nonuniform electric field, having a maximum value of $\alpha^2 F$, where F is the mean field, the following expression has been proposed [29.195]

$$J = \frac{2J_0 kT}{\alpha \beta_{\text{PF}} F^{1/2}} \exp\left(\frac{\alpha \beta_{\text{PF}} F^{1/2}}{k_B T}\right). \quad (29.107)$$

Although this expression was originally proposed for the case of CdTe films, it has also been adopted for the interpretation of results in other materials.

The Poole–Frenkel effect has been observed in many types of thin film, including insulating oxides, semiconductors and organic materials. The main indicator of Poole–Frenkel conductivity is a linear dependence of $\log J$ on $V^{-1/2}$, although it is also seen in the case of the Schottky effect, as will be discussed later. Care must be taken in distinguishing between the two processes. In SiO films, good agreement with (29.106) was obtained [29.196], but the value of β derived exceeded the theoretical Poole–Frenkel value. This type of discrepancy had previously been discussed in the literature [29.197], and it was later proved that in this model the J – V characteristics were symmetric over five orders of magnitude of applied voltage, irrespective of electrode material, which ruled out the Schottky mechanism [29.198]. In another important insulator, silicon nitride, *Sze* [29.199] observed Poole–Frenkel behaviour in metal–insulator–semiconductor (MIS) diodes fabricated on a degenerate Si substrate, over a range of nearly four decades in current. It was found that the current density versus electric field characteristics were independent of film thickness, sample area, electrode materials and polarity, suggesting that the

Fig. 29.24 Linear dependence of the logarithm of current on the square root of the applied voltage in an evaporated Al–CdTe–Al sandwich structure of thickness 722.5 nm at 0 °C (bottom curve), 30 °C, 55 °C, 80 °C and 108 °C (top curve). The behaviour was identified with a form of the Poole–Frenkel effect. After [29.194] with permission from Elsevier Science

conductivity was bulk-limited rather than electrode-limited, and therefore eliminating the Schottky effect. Poole–Frenkel conductivity has also been observed in several semiconducting cadmium compounds, such as RF-sputtered CdS films [29.200, 201] and more widely in CdTe films [29.194, 195, 202]. In Al–CdTe–Al samples, Poole–Frenkel-type conductivity was consistently observed over the temperature range 0–108 °C. These results are typical of Poole–Frenkel behaviour, and are illustrated in Fig. 29.24 [29.194]. However, the value of the experimental field-lowering coefficient increased from $4.95 \times 10^{-5} \text{ eV m}^{1/2} \text{ V}^{-1/2}$ at 0 °C to $7.7 \times 10^{-5} \text{ eV m}^{1/2} \text{ V}^{-1/2}$ at 108 °C, and was about twice the theoretical β_{PF} for CdTe. The Schottky effect was eliminated, as the results did not appear to depend on the electrode workfunction when the Al electrodes were replaced with either In or Ag. These workers adopted the suggestion of *Jonscher* and *Ansari* [29.198] that electrons can hop between sites as the result of thermal activation; on this assumption good agreement was found with the predicted β_{PF} , with an activation energy between hopping sites of 0.15 eV. Very similar results to these were also observed subsequently [29.195], and again the measured value of β exceeded the theoretical Poole–Frenkel value. This coefficient was also calculated from the gradients of the $\ln J-V^{1/2}$ characteristics as a function of temperature, and consistent values were obtained. It was suggested that the similarity between the results of this work and the earlier work [29.194] was related to individual centres experiencing varying electric fields, i.e. the electric field was nonuniform. Equation (29.107) was proposed to account for this effect, and has been successful in accounting for the enhanced coefficients sometimes obtained. Poole–Frenkel conductivity was also identified in p-type CdTe, which also shows a change in conductivity type from SCLC to Poole–Frenkel conductivity [29.203]. This conduction mechanism has also been observed in other cadmium compounds, namely CdSe [29.186] and Cd₃As₂ [29.204]. In phthalocyanine films several instances of this effect have been reported. In oxygen-doped copper phthalocyanine films with a Au and an Al electrode, slightly enhanced values of β were obtained and attributed to a nonuniform electric field, whereas in annealed films the field appeared to be uniform [29.205]. Agreement with the basic model was also found for samples with a Au and a Pb electrode [29.175]. Lead phthalocyanine films with Au and Al electrodes exhibited two different values of β [29.177] consistent with Poole–Frenkel conductivity at higher fields and the Schottky effect at lower fields. However other work-

ers had not considered that Poole–Frenkel conductivity was apparent in the same system [29.206], preferring an interpretation based on two different Schottky barrier widths. Both Schottky and Poole–Frenkel behaviour were observed in oxygen-containing lead phthalocyanine films with two Au electrodes [29.207].

Hopping is a third bulk-limited conduction process which is observed in thin films. This type of conductivity is observed particularly in noncrystalline materials, and is thoroughly discussed in various texts concerned with this topic [29.121, 208]. In this type of material the lack of long-range order results in a phenomenon known as localisation, where the energy levels do not merge into a continuum, particularly in the band-tail regions at the edge of the energy bands. Electrons are transported through the material in a series of jumps or *hops* from one localised energy level to another. The hopping process can occur between the localised energy levels even when only small amounts of thermal energy are available, because the localised levels are normally very closely spaced in energy. For this reason, the process can take place at very low temperatures when other processes are energetically impossible. *Mott* and *Davis* [29.121] argued that the conductivity σ exhibits different behaviour in different temperature regions. At higher temperatures thermal excitation of carriers to the band edges is possible and extended-state or free-band conductivity can take place, while at lower temperatures, where less thermal energy is available, hopping may occur. Different varieties of hopping may take place, and these are distinguished by the length of the hop. Nearest-neighbour hopping is self-explanatory, while in variable-range hopping the hops are on average further than to the nearest neighbour, but the energy difference between the states involved is lower. In the case of variable-range hopping the conductivity has been shown to follow a relationship of the form [29.208]

$$\sigma = \sigma_0 \exp\left(-\frac{A}{T}\right)^{1/4} \quad (29.108)$$

where σ_0 and A are constants. This relationship is known as the Mott $T^{-1/4}$ law, since a plot of $\log \sigma$ against $T^{-1/4}$ shows a linear characteristic with negative slope.

Hopping conduction has been observed in many materials, and is extensively reviewed in the literature [29.121, 208, 209]. The $T^{-1/4}$ law is observed in amorphous Ge [29.210], with the results of *Walley* and *Jonscher* [29.211] also showing this behaviour [29.121]. There is also an example of its appearance in amorphous carbon films [29.212]. AC hopping effects have been observed in several cadmium chalcogenides, and this

work is reviewed elsewhere [29.38]. DC hopping was identified in CdTe films with Al electrodes [29.213] following earlier work on AC conductivity [29.172]. The results suggested a hopping process at temperatures below about 175 K, with a hopping centre concentration of about $9 \times 10^{12} \text{ m}^{-3}$ and a hopping mobility of $2.16 \times 10^{-5} \text{ m}^2/\text{Vs}$, the latter considerably lower than the free-band mobility applicable at higher temperatures. The extent of the electron wavefunction was estimated to be 0.69 nm, corresponding to the lattice parameter in CdTe, and supporting the existence of a nearest-neighbour hopping process. Hopping at lower fields was also identified in CdSe films [29.214] and associated with an impurity conduction process proposed previously [29.215]. Variable-range hopping following the $T^{-1/4}$ law has been observed in iron phthalocyanine and in triclinic lead phthalocyanine films [29.216, 217], although the temperature range was restricted. In the work on iron phthalocyanine the law was followed over the range 140–220 K, with particularly good agreement in the range 156–175 K. In the lead phthalocyanine films similar very good linear behaviour was observed in the temperature range of approximately 220–260 K. Hopping at low temperatures has also been indicated from AC measurements in various phthalocyanine systems [29.218–221].

The first electrode-limited conduction process to be considered is that of tunnelling, which is a quantum-mechanical effect, in which the electron wavefunction is attenuated only moderately by a *thin* barrier, resulting in there being a finite probability of its existence on the opposite side of the barrier. Tunnelling directly from the Fermi level of one electrode to the conduction band of the other is normally possible only for very thin films of thickness less than about 10 nm when subjected to a high electric field. Simmons [29.222] investigated the effects of tunnelling between similar electrodes separated by a thin insulating film of thickness s , where the barrier presented by the film was of arbitrary shape. The Wentzel–Kramers–Brillouin (WKB) approximation was used to predict the probability of an electron penetrating the barrier. Different approximations for the current density were found, depending on the relative values of the applied voltage V and φ_0/e , where φ_0 is the barrier height at the electrode interface and e is the electronic charge. These approximations are too unwieldy to be included here, however for the case of $V > \varphi_0/e$ it is only necessary for electrons tunnelling from the Fermi level of one electrode to penetrate a distance $\Delta s < s$ to reach unoccupied levels in the second electrode. This worker also suggested [29.223] that for $V > \varphi_0/e$ a modified

Fowler–Nordheim [29.224] expression may be applicable for tunnelling through an interfacial region. In this case, the electric field at the barrier is sufficiently high to reduce the barrier width, measured at the Fermi level, to about 5 nm. Under these circumstances the current density is related to the voltage and barrier thickness according to the expression

$$J = \frac{e^3 V^2}{8\pi h \varphi_0 d_t^2} \exp\left(-\frac{8\pi(2m)^{1/2} \varphi_0^{3/2} d_t}{3ehV}\right), \quad (29.109)$$

where h is Planck's constant, φ_0 and d_t are the barrier height and effective thickness, respectively, of the tunnelling barrier and m is the free electron mass. The tunnelling current is largely controlled by the barrier height φ_0 , which appears both in the pre-exponential and in the exponential terms. Fowler–Nordheim tunnelling is indicated by a linear dependence of $\log J/V^2$ on $1/V$. A further interesting point for tunnelling in general is that there is very little temperature dependence in the current density, a feature allowing it to be distinguished from other temperature-dependent mechanisms, such as the Schottky effect. There is in fact a very slight quadratic dependence on temperature [29.164], but this is normally negligible within the limitations of experimental measurement.

Early measurements on tunnelling were made by Fisher and Giaever [29.225] on Al_2O_3 produced by oxidation of Al. There was good agreement with an early tunnelling model [29.226], providing the electron effective mass in the insulator was about 1/9 of the free electron mass. Very thin films of Al_2O_3 and BeO showed ohmic and faster-than-exponential dependencies of J on V at lower and higher voltages respectively [29.227]. These results were correlated with direct metal-to-metal electrode tunnelling at low voltages, and from the Al electrode to the insulator conduction band at higher voltages. The model of Simmons [29.164] was tested by measurements on thermally grown Al_2O_3 films on Al, which used several different types of evaporated counter electrodes [29.228]. An extended tunnelling model [29.229], which is applicable to samples with dissimilar electrodes, was followed over nine decades of current. Measurements on thermally grown SiO_2 films, of thickness 65–500 nm with Al or Au electrodes, showed strong evidence of Fowler–Nordheim tunnelling [29.230]. Since these films were relatively thick, high voltages could be applied, which reduced the Fermi level barrier thickness to that suitable for

tunnelling. A linear dependence of $\log J/V^2$ on $1/V$ was obtained, but the measured currents were somewhat lower than those predicted by the theory, probably as the result of trapping effects. Effective masses of $0.48m$ for Ag, $0.39m$ for Al and $0.42m$ for Si were estimated, where m is the free electron mass. Since these early tunnelling measurements, the mechanism has been observed in many different insulating films.

Tunnelling in semiconductors forms the basis of the operation of the tunnel diode. However, in this case a doubly degenerate p–n junction is used, and tunnelling occurs across the depletion region. The operation of this device is described in a standard text on semiconductor devices [29.231]. In sandwich samples of nondegenerate materials, tunnelling has been observed in CdTe [29.202]. In this case there was a linear dependence of the logarithm of the drift mobility on reciprocal electric field for fields in excess of 1.2×10^6 V/m, which is consistent with (29.109). Tunnelling has also been observed in sandwich structures consisting of a copper phthalocyanine film with In electrodes [29.232]. A modified Fowler–Nordheim expression for tunnelling through an interfacial barrier, when the electric field is sufficient to reduce the barrier width to about 5 nm, has been proposed [29.223], and was applied in this case to the In/Cu phthalocyanine interfacial region. Depending on the sample structure, barrier heights of 0.27 eV and 0.36 eV were derived. Current densities were somewhat lower than predicted by theory, but were accounted for by the fact that tunnelling areas are often considerably lower than the geometric area [29.18] and that in the presence of traps and space charge the current density is also reduced [29.233].

The second electrode-limited conduction process to be considered may occur when the insulating or semiconducting film is too thick for tunnelling to take place and the concentration of allowed states in the forbidden gap is too low for the hopping process to occur. It is known as the Schottky effect, and is the field-assisted lowering of a potential barrier at the injecting electrode. It is similar in origin to the Poole–Frenkel effect, the latter effect having previously been termed the bulk analogue of the Schottky effect [29.234]. The potential barrier at the injecting electrode interface is reduced by an amount $\Delta\phi_S$ which is given by

$$\Delta\phi_S = \beta_S F^{1/2}, \quad (29.110)$$

where

$$\beta_S = \left(\frac{e^3}{4\pi\epsilon_r\epsilon_0} \right)^{1/2} \quad (29.111)$$

is the Schottky field-lowering coefficient. The barrier lowering process is similar to that for the Poole–Frenkel effect, and is also illustrated in various literature reviews [29.164–166]. Differences between the standard Poole–Frenkel and Schottky coefficients given by (29.104) and (29.111) are related to the dissimilar symmetry of the potential barriers in the two cases. Clearly the two field-lowering coefficients are related, with $\beta_{PF} = 2\beta_S$. The fundamental thermionic emission equation of Richardson

$$J = AT^2 \exp\left(-\frac{\phi}{kT}\right) \quad (29.112)$$

gives the current density flowing by a process of electron emission over a potential barrier of height ϕ at a temperature T . In this expression, the constant $A = 1.2 \times 10^6$ A/m², and is known as the Richardson constant. The current density depends only on the potential barrier height and the temperature, and does not require an applied voltage to flow, the electrons acquiring thermal energy only. For the case of Schottky emission, if ϕ_0 , given by (29.91), is the zero-voltage barrier height then the reduced barrier height ϕ is given by $(\phi_0 - \Delta\phi_S)$, so that (29.112) becomes

$$J = AT^2 \exp\left(-\frac{\phi_0}{kT}\right) \exp\left(\frac{\beta_S F^{1/2}}{kT}\right) \quad (29.113)$$

or

$$J = AT^2 \exp\left(-\frac{\phi_0}{kT}\right) \exp\left(\frac{\beta_S V^{1/2}}{kTd^{1/2}}\right). \quad (29.114)$$

Thus, the Schottky effect should show a linear dependence of $\log J$ on $V^{1/2}$, as for the Poole–Frenkel effect described by (29.106). In principle the two effects can be distinguished by the measured value of the field-lowering coefficient, which should be twice as high for the Poole–Frenkel effect as for the Schottky effect.

The Schottky effect has been reported in many inorganic materials, both insulators and semiconductors. *Emtage* and *Tantraporn* [29.235] observed the effect in both Al₂O₃ and GeO₂ sandwich structures having Al electrodes, while *Pollack* [29.236] made similar observations in Al₂O₃ films with Pb electrodes. In this case, not only the constant voltage J – V characteristics were as predicted by (29.114), but the gradients of $\log J$ – $V^{1/2}$ curves increased linearly with reciprocal temperature for temperatures above 235 K, as also predicted by this expression. Below this temperature the variation with temperature was very small, and therefore tunnelling was identified in this region. The dependence of the Schottky effect on the species of electrode was determined in Ta–Ta₂O₅–Au samples prepared by electron

beam evaporation and plasma oxidation [29.237]. In this system the Schottky effect was observed when the Ta electrode was biased negatively and tunnelling when it was biased positively. Similar results were obtained in CdS films [29.169] using In (ohmic) and Au (blocking) contacts. For electron injection from the Au electrode Schottky-type behaviour was observed, with a Schottky barrier height of 0.88 eV obtained from differential capacitance measurements, close to the value expected for Au contacts to CdS single crystals. Field-lowering behaviour has also been observed in Cd₃As₂ films with a bottom Ag electrode and a top electrode of Ag, Al or Au [29.204]. Although the Schottky barrier height is unlikely to be consistent with the simple model of (29.91) owing to the very narrow band gap and the presence of surface states, the experimental value of β was consistent with the value of β_S predicted by (29.111) for a relative permittivity value of 12.

The Schottky effect has also been observed in several organic thin-film materials. Examples are given here only for the phthalocyanines, which are invariably p-type semiconductors. The Schottky effect occurs for hole injection at the blocking contact. Both metal-free [29.238] and copper phthalocyanine films [29.239] having Al electrodes have shown this effect. Behaviour consistent with the Schottky effect has also been observed in planar copper phthalocyanine films with Al electrodes [29.240], with a depletion region width of thickness 96 nm. In sandwich structures having a copper phthalocyanine film and a positively biased Al electrode, values of β several times higher than the theoretical

cal $\beta_S = 2 \times 10^{-5} \text{ eVm}^{1/2}\text{V}^{-1/2}$ were obtained [29.205]. However, if the theoretical value of β_S were assumed and also that most of the voltage was dropped over a depletion region of thickness d_S as suggested previously [29.240], values of $d_S = 120 \text{ nm}$ and $\varphi_0 = 0.88 \text{ eV}$ were derived. This type of assumption has also been subsequently applied in the case of hole injection from a Pb electrode into copper phthalocyanine films [29.175] and for hole injection in triclinic lead phthalocyanine films from an Al electrode [29.177, 206]. In both cases the Schottky barrier width was 50 nm with a barrier height of either 1.11 eV or 1.0 eV.

In this section the main high-field conduction processes that might be observed in insulating and semi-conducting films have been reviewed, and illustrative examples quoted from the literature. It should be emphasised that identification of a particular mechanism is nontrivial, particularly in distinguishing between the Poole–Frenkel and Schottky effects which have very similar J – V dependencies. Furthermore J – V data obtained over a specified voltage range may also show a good correlation with both SCLC and the Poole–Frenkel effect. It is essential to measure temperature dependencies and also to determine the effects of electrode species on the conductivity, making a full consideration of the type of contacts (ohmic or blocking). As devices and structures become ever smaller with the advance of nanotechnology, some of these conduction processes will inevitably become important in nanoelectronic devices. A discussion concerning this aspect is given elsewhere in the literature [29.11].

29.4 Concluding Remarks

In this chapter, an overview of the deposition methods, structures and major properties of thin films has been given. In this section these are briefly summarised and some possible future developments outlined.

Films may be prepared by many different methods. However, these may usually be classified into chemical or physical methods. In the physical methods the film is deposited from a vapour, maintained at a pressure considerably below that of the atmosphere. Vacuum evaporation is the first of these, where the material is transformed into the vapour phase by heating at reduced pressure. Various types of process have been developed to ensure stoichiometry of the deposited material, such as reactive evaporation and co-evaporation. Taken to its limit of sophistication, the method may be operated un-

der UHV conditions using several sources, each of which may be independently controlled. In this case epitaxial films may be deposited, and the method is known as molecular-beam epitaxy (MBE). The second widely used physical method is that of sputtering, which involves the removal of particles (atoms, molecules or larger fragments) from the surface of a target. This is normally achieved using a gas discharge, which delivers high-energy ions to the target surface. Sputtering has several advantages over evaporation, including deposition of stoichiometric materials, better adhesion to the substrate and the capability of depositing most materials. There are several varieties of sputtering, including DC (diode) sputtering, reactive sputtering and RF sputtering, the latter enabling the deposition of insulators as

well as conducting materials. Reactive and co-sputtering give greater flexibility, and higher deposition rates are possible using magnetron sputtering. Various chemical methods may also be utilised for the deposition of films from materials having specific chemical properties. Electrodeposition and electroplating involve passing a high electric current through a solution containing the material, while chemical vapour deposition (CVD) entails the use of various chemical reactions to generate a vapour. The latter method is frequently used in the deposition of electronic materials, and substantial work has been performed in developing processes for several of these. Again there are several different subdivisions of this method, operating at different pressures and with different types of precursor materials. A third chemical method that has found favour in recent years is Langmuir–Blodgett deposition, where molecular layers are applied individually using a dipping process. It has the advantage that high vacuum and elevated temperatures are not required, and film thicknesses are easily derived from the number of layers deposited. It is, however, limited to certain defined materials, and does not have the flexibility of the other methods.

In common with bulk materials, the crystal structure and morphology of thin films may be investigated using diffraction methods and various microscopic techniques (electron microscopy, scanning tunnelling microscopy, etc.). Diffraction methods allow the type of crystal structure to be determined by measurement of the unit cell dimensions in the case of epitaxial and polycrystalline films. Frequently a material may exist in two or more crystalline modifications, and generally these may be distinguished by comparison of diffraction data from the film with tabulated standard data. The type of crystalline modification that is deposited can depend sensitively on the deposition conditions such as the substrate temperature and deposition rate, and this dependence may be established by systematically depositing films under a wide combination of conditions. Many films have a preferred crystalline orientation, and this too may sometimes be correlated with deposition conditions and the substrate morphology. In polycrystalline films, the crystallites are generally preferentially oriented and show a fibre texture. Estimates of the mean microcrystallite size may be obtained from the width of the diffraction peaks using the Scherrer method. The morphological characteristics of thin films commonly have a columnar grain structure when physical deposition methods are used, and the orientation of the grains may sometimes be related to the incident direction of the depositing atoms or molecules. Larger-scale features of

the morphology may often be accounted for in terms of a zone model, where the observed features are identified with the ratio of the substrate temperature to the melting temperature of the film material. Examples of some of these effects in different thin-film materials have been given, and although these are representative of behaviour shown in many thin-film systems, it is clear that both crystal structure and morphology require determination in any specific process used to deposit a particular film material. These features are likely to be particularly important in influencing the optical and electrical properties.

The optical and electrical properties of thin films are those most relevant to this Handbook, and examples of some of the basic properties have been considered as a foundation for some of the more advanced applications described in other chapters. The interference properties of light are fundamental to most of the phenomena observed. In principle the properties of light propagating through media are described by Maxwell's equations, which allow a full analysis for both nonabsorbing and absorbing films for various states of polarisation and optical frequencies. The Fresnel coefficients for reflection and transmission of light at the boundaries between different optical media allow expressions for the energy reflectance and transmittance to be derived. Some examples of these have been given, together with an introduction to matrix methods which may be used to calculate the electric and magnetic field vectors for optical designs of considerable complexity, involving both nonabsorbing and absorbing films. The operation of optical filters, other optical components and fibre-optic waveguides may be predicted by advanced application of these methods. Examples of the basic electrical properties of thin films, which are directly related to the film thickness, are lateral electrical conductivity and high-field conduction processes. Lateral electrical conduction in thin films is a very important feature, which is determined primarily by electron scattering within the film. For metallic films, conductivity–film thickness relationships have been derived in terms of a parameter k , the ratio of the film thickness to the bulk electron mean free path. One would intuitively expect the conductivity to decrease (or the resistivity to increase) with decreasing k , since this implies a curtailment of the mean free path. This problem was first tackled over a century ago by Thomson, and more realistic expressions have been obtained subsequently by solving the Boltzmann transport equation. Unfortunately, the derived general expressions are somewhat complex, but a wide variety of approximations have been obtained for various ranges of k ,

and the conductivity is predicted to reduce to that of the bulk material for thick films. Further refinements in the analysis were made by introducing a specularly parameter, p , which takes into account the proportion of electrons which are specularly scattered at the surfaces. Better agreement with experimental results is generally obtained if the value of p is intermediate between that for totally diffuse scattering ($p = 0$) and totally specular scattering ($p = 1$). Another development of the theory includes assigning different specularly parameters to the two film surfaces, since scattering at the substrate surface is clearly different from scattering at the top surface. In general the various expressions derived from this type of model are consistent with each other, in that those derived from the more complex assumptions normally reduce to those obtained using simpler assumptions if suitable limits are chosen. Scattering by internal grain boundaries has also been investigated by solving the Boltzmann transport equation, and allows contributions to the conductivity resulting from internal features, as well as the surfaces, to be included in the analysis. The ratio of the thin-film to bulk temperature coefficient of resistivity has been shown to be equal to the ratio of thin-film to bulk conductivity for the case of thicker films, although no such convenient relationship applies for thinner films owing to the dependence of the bulk mean free path on temperature, which is particularly significant for very thin films. Considerations of these types of effect need to be fully assessed when designing interconnects to integrated circuits operating in particular temperature ranges. In insulating or semiconducting thin films, very high electric fields may be applied across the thickness of the film. Under these circumstances a variety of different conduction processes may occur, none of which are observed at lower fields. Crucial to the type of conduction process which develops is the type of contact at the interface. Ohmic contacts allow currents to pass unimpeded by the contact, and the conduction process is bulk-limited, while blocking contacts effectively limit the conductivity, which is then electrode-limited. Bulk-limited conduction processes include SCLC, Poole–Frenkel conductivity and hopping. Various types of SCLC have been observed, depending on the type of trap distribution present, if any, and may be distinguished by their characteristic voltage and temperature dependencies. Poole–Frenkel conductivity results from field-dependent lowering of the potential barrier for emission of electrons into the conduction band. Again, various varieties of this process have been observed depending on the appearance of donors and/or traps, and also for the case of nonuniform

fields. Hopping is observed particularly in noncrystalline solids, where electrons hop from one localised energy level to another. It is characterised by low mobility, but requires little thermal energy, and is therefore often observed at low temperatures. Different types of hopping are characterised by the mean distance of the electron hopping process, and show different characteristic behaviours. Electrode-limited conduction processes include tunnelling and the Schottky effect. Tunnelling is a quantum-mechanical effect, where for a thin barrier the electron wavefunction has a finite probability of existence on the opposite side of the barrier. Tunnelling may be either directly from one electrode to the other, or may be from the Fermi level of the injecting electrode into the conduction band of the insulator or semiconductor. The type of tunnelling depends on the relative values of the applied voltage and the barrier height at the interface. The tunnelling current is almost independent of temperature, a feature which allows it to be identified relatively easily. For structures where the barrier is too thick for tunnelling to occur, the Schottky effect may take place instead. This is the field-assisted lowering of a potential barrier at the interface, and has several similarities with the bulk Poole–Frenkel effect. Similar J – V characteristics are predicted for both, but may usually be distinguished from the value of a measured field-lowering coefficient, or from considerations of the current level drawn with varying electrode species.

In conclusion, it should be noted that in this chapter only the main established deposition methods and some of the structural, optical and electrical properties of thin films have been reviewed. Although it is hoped that the references included herein are sufficient to allow the reader to explore the subject in some considerable depth, it is clear that these can only provide a snapshot of knowledge at the present time. During the past half century, there have been tremendous developments in all areas of thin-film knowledge, although the basic principles and properties stressed in this chapter underpin most of them. The main physical methods of deposition have been known for a century or so, but improvements have been contingent on advances in vacuum technology, gas-handling capabilities and theoretical work concerning atomic interactions in solids. MBE deposition systems of considerable complexity and sophistication now exist, enabling the deposition of a considerable range of materials in a variety of structures and designs, although only some of the most important processes have been developed to the level where they are employed in automated manufacture. Control of many factors are vital in successful deposi-

tion processes, and progress in this area has gone hand in hand with the development of computerised monitoring and data-handling systems. Progress in the manipulation of individual atoms and molecules has been made by the adoption of techniques originally developed for very high-resolution surface imaging, such as scanning tunnelling and atomic force microscopy. Chemical methods of film deposition have developed into many dedicated CVD systems, exploiting reactions which are specific to a particular material or class of materials. Additionally many types of films may be deposited using the Langmuir–Blodgett technique, although this relies on the ingenuity of chemists to develop suitable substituted organic compounds. Further development of many of these deposition methods will undoubtedly progress in future years, particularly as the power of computer systems increases. The most significant advances are likely to be in the area of nanotechnology, where MBE systems, equipped with facilities to build nanostructures atom by atom, are currently under development. The structure and morphology adopted by thin films are likely to have a significant influence on all their properties; this is not restricted to just the optical and electrical properties described in this chapter. Diffraction methods are becoming more precise, and can now be used for the investigation of real-time changes when synchrotron radiation is used. Scanning tunnelling and atomic force

microscopic techniques have enabled the acquisition of surface images with resolution of atomic dimensions, and the increased use and development of these and associated techniques will be necessary for future investigation of nanostructures. Optical properties described in this chapter will no doubt be exploited in more complex and sophisticated filter and mirror designs, as well as their employment in fibre-optic cables and applications in photonics. Recent developments in the area of negative-refractive-index materials will no doubt also be exploited in due course. The electrical properties of thin films under both low- and high-field conditions are reasonably well understood, and it is anticipated that applications are likely to be made in the area of nanoelectronics. Some possible applications have been proposed elsewhere [29.11]. The provision of electrical contacts will remain of particular importance, although it may not be possible to consider the contact region separately from the remaining nanostructure. The efficient injection of charge into nanostructures using tunnelling and Schottky barrier (blocking) contacts may be achieved, and high current densities may be obtained with trap-free SCLC contacts. It is nevertheless clear, however, that in all areas of future development in thin-film technology, the control of deposition processes and materials processing aspects are of paramount importance. This is likely to remain a considerable challenge in the future.

Thick Films

30. Thick Films

Thick film technology is an example of one of the earliest forms of microelectronics-enabling technologies and it has its origins in the 1950s. At that time it offered an alternative approach to printed circuit board technology and the ability to produce miniature, integrated, robust circuits. It has largely lived in the shadow of silicon technology since the 1960s. The films are deposited by screen printing (stenciling), a graphic reproduction technique that can be dated back to the great Chinese dynasties of around a thousand years ago. Indeed, there is evidence that even early Palaeolithic cave paintings from circa 15 000 BC may have been created using primitive stenciling techniques. With the advent of surface-mounted electronic devices in the 1980s, thick film technology again became popular because it allowed the fabrication of circuits without through-hole components.

This chapter will review the main stages of the thick film fabrication process and discuss some of the commonly used materials and substrates. It will highlight the way in which the technology can be used to manufacture hybrid microelectronic circuits. The latter stages of the chapter will demonstrate how the technology has evolved over the past twenty years or so to become an important method in the production of solid state sensors.

The term “thick film” is often misinterpreted, and so it is worth noting from the outset that it has little to do with the actual thickness of the film itself. The preferred definition encompasses the fabrication process, namely screen printing, used to deposit the films. The typical range of thicknesses for thick film layers is 0.1 μm to 100 μm . Screen printing is one of the oldest forms of graphic art reproduction and involves the deposition of an ink (or paste) onto a base material (or substrate) through the use of a finely-woven screen with an etched pattern of the desired geometry. The process is commonly used for the production of graphics and

text onto items such as T-shirts, mugs, pencils, textiles and so on, and is very similar to that used for micro-electronic thick films. The degree of sophistication for the latter is, however, significantly greater, resulting in high-quality, reproducible films for use in a variety of electronic systems.

The technology used to manufacture thick film hybrid microelectronic circuits was introduced in the 1950s. Such circuits typically comprised semiconductor devices, monolithic integrated circuits, discrete passive components and the thick films themselves [30.1, 2]. In the early days of the technology, the thick films were

mainly resistors, conductors or dielectric layers. Evidence of thick film circuits can still be found in many of today's commercial devices such as televisions, calculators and telephones. The use of thick film technology was overshadowed in the 1960s by the impact of silicon technology. It found popularity again in the 1980s as a result of the advent of surface-mounted devices, which can be attached to circuit boards using screen-printed solder

layers. Nowadays, thick films are not only used in hybrid circuits but also in advanced solid state sensors and actuators, as we shall see later. In broad terms, thick films can be classified as either *cermets* (ceramic/metallics), requiring high-temperature processing, or *polymer* thick films, which are cured at significantly lower temperatures. Polymer thick films will be covered in more detail in Sect. 30.3.4.

30.1 Thick Film Processing

Thick film technology is sometimes referred to as an *additive* technology in that the layers are built up in sequence without the need to remove (or subtract) parts of the film by techniques such as etching. Compare this with, say, a standard printed circuit board (PCB), where the conductive tracks are formed by selectively etching away the undesired areas (gaps) from a continuous copper layer. In the early days of the technology, the ability to fabricate together components made with different enabling technologies to produce a *hybrid* circuit was seen as a way of opening up a whole new field of electronics. This is still one of the most endearing features of the technology today.

30.1.1 Screen Printing

This is the distinguishing feature of thick film technology and is the method of depositing the desired films. The fundamental aspects of the process, traditionally recognized as an art, have been modernized and updated to provide a scientific tool for microelectronic technology. Figure 30.1 illustrates the main aspects of the screen printing process [30.3].

The screen fabric is permanently attached to the screen frame, which is firmly held within the screen printing machine. The distance between the screen and the substrate is typically around 0.5 mm, although the

Fig. 30.1 The basic screen printing process

Fig. 30.2 A plain weave screen mesh

precise gap size is dependent on the overall screen dimensions. The substrate is held in place in the holder by either a vacuum or a mechanical clamp. The position of the screen can be finely adjusted to ensure good registration between consecutive layers. The paste is applied to the upper surface of the screen and the flexible *squeegee* is pulled across the screen over the ink, which is forced through the open areas of the screen mesh. At a point immediately behind the squeegee, the screen peels away from the substrate and, due to the surface tension between the ink and the substrate, leaves a deposit of the paste in the desired pattern on the substrate.

The squeegee is a flexible blade whose function is to transfer the ink through the screen and onto the substrate. It is usually made from materials such as polyurethane or neoprene. The squeegee pressure is adjustable and facilitates accurate and repeatable print thicknesses. The pastes generally exhibit pseudoplastic behavior in that

the viscosity varies with the applied shear force. This is a necessary property because the ink must have minimum viscosity to ensure good transfer through the screen, but it also must become more viscous after printing to provide a good definition of the film.

The function of the screen is to define the pattern of the printed film and also to control the amount of paste being deposited. The screens used in graphic artwork are generally made of silk and the process is often termed silk screen printing. For microelectronic circuits, however, the screens tend to be made from polyester, nylon or stainless steel. The resolution of the printed line widths is largely determined by the mesh count (in lines per inch or centimeter) and the mesh filament diameter. Nylon has very good elastic properties but relatively poor resilience. Stainless steel screens produce excellent line definition and durability and are particularly well suited to flat substrates. Polyester screens have the highest resilience and offer a long lifetime and low squeegee wear. Figure 30.2 shows a plain weave pattern on a typical thick film screen. An ultraviolet (UV)-sensitive emulsion covers the underside of the screen. The desired pattern is formed onto screen emulsion using a photographic process. The screen printing process can be used to deposit both cermet and polymer thick films; the processing steps that follow are, however, different.

30.1.2 The Drying and Firing Process

The final form of a cermet thick film is a fired, composite layer that is firmly attached to the substrate. Essentially, there are three main stages in the production process: screen printing, drying and firing. At each of these stages, the film is in a slightly different state. Commercial thick film pastes are purchased from the manufacturer in plastic jars and are similar to standard printing inks in many respects. The three main components in a thick film paste are:

- The active material;
- A glass frit;
- An organic vehicle.

The active material is a finely ground powder with a typical particle size of a few microns. A conductor paste, for example, will contain a precious metal or metal alloy. The glass frit serves as a binder that holds the active particles together and also bonds the film to the substrate. The organic vehicle is necessary to give the paste the correct viscosity for screen printing. It usually contains a resin dissolved in a solvent together with a surfactant that ensures good dispersion of the solid particles.

After screen printing, it is usual to allow the film to stand in air for a few minutes to let the paste level off. The film is then dried in an infrared belt drier or a conventional box oven at temperatures up to 150 °C. The purpose of drying is to remove the organic solvents so that the film and substrate can be handled during further processing steps. After drying, the films then proceed to the firing stage. In some circumstances, however, they may be overprinted with another thick film layer if the nature of the film allows this.

The high-temperature firing cycle performs three main functions: the remaining organic carrier is removed from the film, the electrical properties are developed, and the film is bonded to the substrate. In order to achieve these, it is necessary to subject the films to temperatures of up to 1000 °C in a moving belt furnace. Inside the furnace there are several heating zones, which can be independently controlled to a profile specified by the paste manufacturer. Figure 30.3 shows a typical firing profile that is used with commercial thick film resistor pastes. The substrates enter the furnace on a metal chain mesh belt at ambient temperature and slowly (at a rate of a few centimeters per minute) travel through the heating zones, which have their temperatures set to form the desired profile. The substrates remain at the peak temperature for about ten minutes and the electrical properties of the film are formed during this phase. Most thick film materials are fired in a clean, filtered air atmosphere, as this produces high-quality films with repeatable characteristics. Occasionally, however, it is necessary to provide an inert atmosphere such as nitrogen, so that materials such as copper can be processed.

Fig. 30.3 A typical thick film firing profile with a peak temperature of 850 °C

30.2 Substrates

The main functions of the substrate are to provide mechanical support and electrical insulation for the thick films and hybrid circuits. Some of the main considerations for selecting substrates are listed below:

Dielectric constant: This determines the capacitance associated with different elements fabricated onto the substrate. The dielectric strength will also determine the breakdown properties of the substrate.

Thermal conductivity: Substrates with a high thermal conductivity can be used in applications where the circuit generates significant amounts of heat.

Thermal coefficient of expansion (TCE): In general terms, the TCE of the substrate should be closely matched to the thick film materials and other components mounted on it. In some cases this cannot be assured, and in this case the consequences (in terms of thermal strains) must be fully considered.

The main substrate materials used in thick film technology are the ceramic materials alumina (Al_2O_3), beryllia (BeO) and aluminium nitride (AlN). Enamelled or insulated stainless steel substrates are sometimes used in some applications. Silicon has also been used in specialist transducer applications. Alumina, however, is the most common substrate material and it possesses desirable physical and chemical properties in addition to providing an economical solution. Alumina of 96% purity is used in the vast majority of worldwide commercial circuits. The remaining 4% weight fraction of the content is made up of magnesia and silica, which improve the densification and electrical properties. Beryllia has a high thermal conductivity and is used in applications where rapid heat removal is required. It is, however, a very toxic material and is therefore only used in limited application areas. Aluminium nitride is, essentially, an alternative for beryllia, with a high thermal conductivity and also improved mechanical properties such as higher flexural strength. Insulated stainless steel substrates are sometimes used in applications where a high thermal dissipation and mechanical ruggedness are required. They are particularly well suited to mechanical sensor applications.

30.2.1 Alumina

Alumina substrates are manufactured by blending alumina powder, with an average particle size of around $1\text{ }\mu\text{m}$, together with small amounts of silica, magnesia and calcia. These are either ball- or roll-milled for about 10 h with lubricants, binders and solvents that en-

sure thorough mixing. Most thick film substrates are less than one millimeter thick, and the preferred method of fabrication is sheet casting. A slurry is allowed to flow out onto a smooth belt, and it passes under a metal doctor blade which controls the resultant thickness. The material is then dried in air to remove the solvent and, at this stage, it is sometimes referred to as the *green state* because of its color. The substrates are then fired in a kiln for at least 12 h. A peak temperature of around 1500°C ensures that the materials are properly sintered. During firing, the substrates can shrink by up to 20%, and this needs to be taken into consideration for the formation of the final substrate. The surface finish can be improved by coating the surface with a thin, glassy layer (glazing), which is done as an additional step at a lower temperature.

30.2.2 Stainless Steel

Stainless steel is a strong, elastic material with a relatively high thermal conductivity. Being a good electrical conductor, the steel must be coated with an insulating layer before it can be used as a substrate for thick film circuits. Porcelain enamelled steel substrates are made by coating a stainless steel plate with a glassy layer between 100 and $200\text{ }\mu\text{m}$ in thickness. The steel is enamelled either by dipping, electrostatic spraying or electrophoretic deposition of a low-alkali glass and subsequent firing at several hundred degrees Celsius. Some commercial paste manufacturers produce an insulating dielectric thick film ink that can be screen printed directly onto various types of stainless steel. The substrates are fired at a temperature of around 900°C . The paste contains a devitrifying glass that does not recrystallize on further firings and therefore provides compatibility with other standard thick film materials. Insulated stainless steel substrates also offer the advantages of having a built-in ground plane (the steel itself) and excellent electromagnetic and electrostatic shielding properties. It is also possible to machine the substrate, using conventional workshop facilities, prior to the circuit fabrication.

30.2.3 Polymer Substrates

In some applications it is desirable to fabricate a circuit onto a flexible substrate; evidence of these can be found in mobile telephones, calculators and notebook computers. Cermet thick film materials are not compat-

ible with flexible substrates and hence special polymer thick film materials are used (Sect. 30.3.4). Polymer substrate materials are mainly based on polyesters,

polycarbonates and polyimide plastics. The maximum processing temperature is usually limited to around 200 °C.

30.3 Thick Film Materials

30.3.1 Conductors

Thick film conductors are the most widely used material in thick film hybrid circuits. Their main function is to provide interconnection between the components in the circuit. For a multilayered circuit, the conductor tracks are separated by dielectric layers and connection between each layer is achieved with metallized vias. Conductors are also used to form attachment pads for surface-mounted components such as integrated circuits or discrete passive components (resistors, capacitors and inductors). They can also be used as bond pads for naked dice, which may be attached directly to the thick film circuit. Another function of conductors is to provide the terminations for thick film resistors. With such a diverse range of applications, it is no surprise that a wide range of conductor materials is available.

The characteristics of thick film conductors are dependent upon the composition of the functional phase of the paste. Typically, these comprise finely divided particles of precious metals such as silver, gold, platinum or palladium. Base metals such as aluminium, copper, nickel, chromium, tungsten or molybdenum are also used. The particle size, distribution and shape also have an effect on the electrical and physical properties of the fired film.

The resistance of a conductor film is given by

$$R = \frac{\rho l}{wt},$$

where ρ is the bulk resistivity ($\Omega \text{ cm}$), l and w are the length and width of the conductor respectively, and t

is the fired thickness of the film. The term *sheet resistivity* is often used for thick films and is defined as the bulk resistivity at a given thickness (ρ/t), expressed in ohms per square (Ω/\square). This is convenient because the resistance of the track can then be calculated by simply multiplying the sheet resistivity by the aspect ratio (l/w) of the film. Table 30.1 summarizes some of the most common metals and metal alloys used in thick film conductors together with their sheet resistivities.

Silver Conductors

Silver pastes were one of the earliest thick film conductors to be developed. They possess good bond strength and high conductivity. There are, however, several disadvantages to using pure silver which prevent it being widely used in many applications. These include:

- Poor leach resistance to solder;
- Oxidation in air over time;
- Susceptible to electromigration in the presence of moisture, elevated temperature and bias voltage.

Silver/palladium conductors

The alloy of silver and palladium is the most common type of thick film conductor and is the alloy most widely used in the hybrid circuit industry. It can be used for interconnecting tracks, attachment pads and resistor terminations, but is generally not recommended for wiring bonding pads. Silver/palladium conductors overcome many of the problems associated with pure silver, and low-migration formulations are available from several commercial suppliers.

Gold Conductors

Gold pastes have a high conductivity and are mainly used in applications where high reliability is required. Gold is a particularly good material for wire bonding pads, although it has relatively poor solderability. Gold is a precious material and hence very expensive; it is therefore not used for general purpose applications and is limited to those areas that can justify the higher costs.

Table 30.1 Most of the common metals and metal alloys used in thick film conductors and their sheet resistivities

Metallurgy	Sheet resistivity ($\text{m}\Omega/\square$)
Silver (Ag)	1–3
Gold (Au)	3–5
Copper (Cu)	2–3
Silver/palladium (Ag/Pd)	10–50
Gold/palladium (Au/Pd)	10–80
Gold/platinum (Au/Pt)	50–100

Copper Conductors

Copper thick films have to be processed in an inert atmosphere; nitrogen is typically used in this case. Copper is widely used as the conductor material for printed circuit boards owing to its good electrical conductivity and solderability. These features are also applicable to thick film copper conductors, which also offer ability to handle larger currents than most other thick film conductors.

Platinum Conductors

Not too surprisingly, perhaps, these are the most expensive of all the commercial thick film conductor materials. Platinum films have a very high resistance to solder leaching and exhibit similar electrical properties to those of the bulk material: a linear, well-defined temperature coefficient of resistance (TCR). Platinum films are therefore used in specialist applications such as heaters, temperature sensors and screen-printed chemical sensors.

Gold Alloy Conductors (Au/Pd, Au/Pt)

These have good bond strength, good solder leach resistance and are relatively easy to solder. The conductivity of the gold alloys tends to be inferior to that of the other type of thick film conductor, but they can be used with both ultrasonic (aluminium) and thermosonic (gold) wire bonds.

Once the conductor has been fired, a composite structure is formed. Figure 30.4 shows a simplified view of the cross-section of a fired thick film conductor on a substrate. Many of the metallic particles have joined together to make a continuous chain. The glass is mainly evident at the interface between the bulk of the film and the substrate. The presence of voids (gaps), both within the film and on its surface, can also be noted.

30.3.2 Resistors

Resistor inks consist of a mixture of the three main phases listed earlier. The relative proportions of the active material to glass frit can have a dramatic effect on the electrical properties of the fired film. The earliest resistors were made from materials such as carbon, silver and iron oxide and were found to suffer from poor long-term stability, unpredictability of fired resistivity, and unacceptably high temperature coefficients. Modern thick film resistor systems are mainly based on ruthenium dioxide (RuO_2) and have much-improved characteristics. This material has a high conductivity and is extremely stable at high temperatures. Within the resistive paste, the conductive phase comprises submicron

Fig. 30.4 Idealized cross-sectional view of a cermet thick film conductor

particles, and these are mixed with larger glass particles (several microns in diameter). Various additives are added to the formulation to improve the stability and electrical properties of the fired film. The nature of these additives is proprietary knowledge of the paste manufacturer.

Figure 30.5 shows an idealized cross-section of a thick film resistor fabricated onto a substrate. The end terminations are first printed and fired and then the resistor is formed in the same manner, allowing for a slight overlap on the terminations so that small misalignments during the printing of the resistor can be accounted for. The actual surface profile of a real resistor would show a nonuniform thickness across its length.

Commercial thick film resistor pastes are available in a range of sheet resistivities from 1 to $10^9 \Omega/\square$, and the value of the fired resistor is determined by the selected sheet resistivity and the ratio of the length to the width, as previously described for conductors. For example, a $10 \text{ k}\Omega$ resistor could be made by printing a square ($l = w$) of $10 \text{ k}\Omega/\square$ resistor paste. Similarly, a $5 \text{ k}\Omega$ resistor requires an aspect ratio of 1 : 2 ($l : w$) if printed with the same paste. Note that the absolute value of a thick film resistor is not limited to a preferred value, as is the case for discrete resistors.

Figure 30.6 shows the temperature dependence of resistance for a typical thick film resistor. The shape of

Fig. 30.5 An idealized cross-section of a thick film resistor

the plot is unusual because there is a point at which the resistance is a minimum (T_{\min}). In general terms, the sensitivity of a resistor to temperature is denoted by the temperature coefficient of resistance (TCR). Mathematically, this can be expressed by

$$\text{TCR} = \frac{\Delta R/R}{\Delta T},$$

where $\Delta R/R$ is the relative change in resistance and ΔT is a small change in temperature. Metals generally exhibit an increase in resistance with increasing temperature, so the TCR is positive. A thick film resistor appears to have both a positive and negative TCR at different regions of the resistance versus temperature curve [30.4]. The point of minimum resistance occurs around room temperature, which means that the resistance is stable under normal operating conditions. It is common practice to refer to the 'hot' and 'cold' TCR for the regions above and below T_{\min} , respectively.

The long-term stability of thick film resistors in air at room temperature is excellent, with a typical change of less than 0.2% over 10^5 h (about 100 years!). At elevated temperatures the stability is still impressive, with most resistance values changing by only 0.5% over 1000 h at 150 °C. The tolerance of fired resistors is around $\pm 20\%$ due to a variety of reasons, including variations in resistor thickness, the tolerance on the quoted sheet resistivity and the effects of the firing process. If accurate values of resistance are required, it is therefore necessary to trim the resistor. This is achieved by removing areas of the resistor with either an air-abrasive jet or a laser. Resistor values can only be increased by trimming, so the printed value is always designed to be less than that of the post-trimmed value.

Fig. 30.6 A plot of relative resistance change against temperature for a thick film resistor

30.3.3 Dielectrics

Dielectric pastes have four main uses in thick film hybrid circuit applications:

- Cross-over insulators for multilayer circuits;
- Thick film capacitor dielectrics;
- Passivation layers;
- Insulation layers for stainless steel substrates.

Cross-over dielectrics comprise a ceramic material such as alumina, together with the usual glass frit and organic vehicle. These films are required to have a low dielectric constant in order to minimize capacitive coupling between the conducting tracks. They must also have a good insulation resistance and a smooth, pinhole-free surface finish.

There is an occasional requirement to fabricate thick film capacitors, although the wide availability of surface-mounted capacitors has largely precluded their need. It is also difficult to ensure that post-fired values of thick film capacitors closely match those for which they were designed. An expensive trimming process is needed to ensure that the correct values are obtained.

Overglazes are mainly used to protect resistors from overspray during trimming and also the circuit from environmental attack during operation. The passivation layer is usually the last one to be processed and it is therefore fired at a reduced temperature in order to minimize any adverse refiring effects on other layers. Overglaze materials are therefore almost exclusively made from low-temperature glasses that fire at temperatures of 450 to 500 °C.

The use of insulated stainless steel substrates was mentioned earlier. The dielectric materials used for this purpose must provide a high insulation resistance (in excess of $10^{12} \Omega$) and also possess a high breakdown voltage (greater than 2 kV/mm). There is an inherent mismatch between the thermal coefficient of expansion of the metal substrate and that of the insulation layer, which limits the type of steels that can be used for this purpose.

30.3.4 Polymer Thick Films

The processing temperatures for polymer thick films are significantly less than those needed for cermet materials. Rather than being 'fired', polymer materials are cured at temperatures below 200 °C. One advantage of polymer thick films over cermets is a reduction in processing and material costs. As with cermet pastes, the formulation of polymer thick films comprises the active

material, a polymer matrix and various solvents. The polymer matrix acts as ‘glue’ for the active component. Three types of polymer organic composition are used in polymer thick films:

- Thermoplastic;
- Thermosetting;
- Ultraviolet (UV)-curable.

With thermoplastics, the required viscosity for screen printing is achieved via solvents. The polymer material is typically acrylic, polyester, urethane or vinyl. After printing, the paste is hardened by drying in a belt or box oven. These types of film have relatively poor resistance to environmental conditions and are not resistant to elevated temperatures and solvents. Thermosetting pastes have polymers that are partially cured and are typically epoxy, silicone or phenolic resin. After printing, the polymer is fully cured, providing a strong and stable matrix. Solvents are still needed to provide the correct rheology for printing. The UV curable pastes are generally used for dielectric inks and can be cured at room temperature under an ultraviolet light source.

For conductors, the most commonly used active phases are silver, copper and nickel. Owing to their poor stability at high temperatures, polymer thick film conductors cannot be soldered and alternative forms of attachment must be adopted. Carbon is typically used as the active material in polymer thick film resistors. The performance of these resistors is inferior to that of their cermet counterparts and they are therefore seldom used in critical applications. The dielectric pastes are similar in nature to conductors and resistors except that the conducting phase is omitted from the formulation. Some manufacturers add minerals to improve the electrical and mechanical properties of the dielectric films. Polymer thick films are a popular choice of material for disposable biosensors such as those used in

Fig. 30.7 A selection of flexible circuits (courtesy of Flex Interconnect Technologies, Milpitas, USA)

the home testing of levels of glucose in human blood samples.

The process for fabricating polymer thick films is similar to that used with cermet materials. Once they have been screen printed, the layers are left to stand in air for a few minutes to ensure that the surface is level and contains no residual mesh patterns. The curing process is achieved in a box oven or an infrared belt dryer at temperatures in the range 150–200 °C. For a thermoset polymer, the higher the temperature and longer the curing time, the greater the cross-linking of the polymer chains in the matrix. This can lead to improved film stability and increased shrinkage.

An early and successful application of polymer thick film technology was the fabrication of membrane switches for keyboards. Today, examples of polymer thick film circuits can be found in many consumer products, such as mobile phones, portable computers, personal digital assistants and calculators. Figure 30.7 shows some typical flexible polymer circuits.

30.4 Components and Assembly

30.4.1 Passive Components

Passive electronic components are those that do not require an external energy source to function. Examples are resistors, capacitors and inductors. As we have seen earlier, thick film technology allows the fabrication of high-quality, stable resistors. It is also possible to add resistors to a thick film circuit in the form of an additional chip component. Such devices are

available as surface-mounted devices, which do not require holes to be drilled into the circuit board. Interestingly, chip resistors are often manufactured as multiple parts using thick film techniques on ceramic substrates. These are then diced and the terminations are added. An example of a typical chip component is shown in Fig. 30.8. Resistor values can range 1 Ω to 10 MΩ, with typical tolerances of between ±1% to ±20%.

Planar screen-printed capacitors are rarely used in thick film hybrid circuits owing to their poor stability and high production costs. They typically comprise at least three layers (two electrodes and one dielectric layer), and trimming is often required to achieve the target value of capacitance. Chip capacitors offer improved performance at a lower cost. Capacitances in the range 1 pF to 100 μ F are readily available in a range of sizes from the 0201 series (0.6 mm \times 0.3 mm \times 0.3 mm) to the 2220 series (5.7 mm \times 5.0 mm \times 3.2 mm). Chip inductors are also available (typical range: 0.1 μ H to 1000 μ H) in a variety of package sizes. There is also a wide choice of variable passive components such as potentiometers and variable capacitors/inductors that are currently available from many major component suppliers.

30.4.2 Active Components

Active components are those that require an external energy source to function. Examples are transistors, diodes

Fig. 30.8 A typical surface-mounted chip component

Fig. 30.9a–c Examples of surface-mounted packages (a) SOT-23 package (b) Small outline (SO) package (c) Flatpack package

and semiconductor integrated circuits. A wide variety of semiconductor components are available to the thick film circuit designer. Transistors and diodes, being relatively small devices, are obtained in a small plastic package with three terminals. This is known as a SOT-23 package and is shown in Fig. 30.9a. Many standard integrated circuits that are available in dual-in-line (DIL) packages for through-hole printed circuit boards are also available in small outline (SO) packages for hybrid circuits. An example of a small outline device is shown in Fig. 30.9b, and these usually have between 8 and 40 pins. For devices with higher pin counts such as microprocessor, gate arrays and so on, it is usual to place the leads on all four sides of the package, as with the flatpack device shown in Fig. 30.9c. Occasionally, ICs may be obtained in the form of a naked die, without any packaging. In such cases, it is necessary to glue the chip to the board and to bond very fine wires from the chip to the board. Care has to be taken to ensure that the naked device is suitably encapsulated for use afterwards.

Other forms of IC include flip chips, which are essentially naked chips with raised connection contacts (bumps) made of solder, gold or aluminium. These are mounted by turning over the chip (flipping) and bonding directly to the substrate. Beam lead chips also examples of naked dice with either gold or aluminium leads protruding from the edge. The leads (beams) are an integral part of the chip metallization process. Such devices are usually passivated with a layer of silicon nitride during processing. Tab automated bonding (TAB) refers to a technique by which the naked chip is attached to metallized fingers on a continuous strip of film. Large quantities of devices can be produced on a single roll and the leads of the devices are welded onto the boards before the carrier film is removed. In this manner, it is possible to achieve good yields on high-density circuit populations.

30.4.3 Trimming

The tolerance on the printed value of thick film components such as resistors is around $\pm 20\%$ of the desired value. Many applications require a much tighter tolerance, and so the components need to be trimmed. The two most popular techniques used are trimming by laser or by an air-abrasive jet. Both of these are capable of producing resistors with a tolerance of $\pm 0.1\%$. Laser trimming, however, is more amenable to large-scale component adjustment.

Air-abrasive trimming uses a pressurized jet of air containing a fine abrasive powder to remove a small

Fig. 30.10a–e Examples of trim cuts for resistors (a) Straight cut (b) L-cut (c) Double cut (d) Serpentine cut (e) Top hat

area of the fired thick film. The diameter of the jet nozzle is around 0.5 to 1 mm. Alumina particles of average diameter 25 μm are often used as the abrasive medium. The substrate containing the component to be trimmed is held underneath the nozzle at a distance of around 0.6 mm and electrical probes are attached to the device. During trimming, the particles in the jet stream remove material from the component. The debris is removed from the substrate by a vacuum exhaust system. In the case of resistor trimming, the value can only increase because the material is being removed. Resistor values cannot be reduced by the trimming process. For this reason, resistors requiring trimming are designed to be between 25 and 30% lower than the post-trimmed value.

Laser trimming has the advantage of offering a fully automated, high-speed way of adjusting component values. The thick film is vaporized with high-energy laser beam pulses. The laser is typically a Q-switched neodymium-doped YAG (yttrium aluminium garnet) type. A single pulse removes a hole of material and a line is achieved by overlapping consecutive pulses.

Resistors are the most common component requiring trimming. Sometimes conductor tracks need to be adjusted in special circumstances. For example, a platinum conductor being used as a classic Pt 100 resistance thermometer must have a resistance of 100 Ω at 0 $^{\circ}\text{C}$. In rare circumstances, thick film capacitors can be trimmed by removing an area of one of the plates, although the post-trimmed stability is poor.

Figure 30.10 shows some examples of different types of cut that can be used to trim resistors. The straight cut is the fastest way to trim, but it does not provide a reliable way of achieving a high accuracy. The L-cut overcomes this problem; the resistor is first trimmed straight and then the cut runs parallel to its length, providing a finer adjustment of the value. Both the serpentine and double cut require additional cuts perpendicular to an initial straight cut. The top hat structure is used in situations where a large change in resistance is needed.

30.4.4 Wire Bonding

When a naked integrated circuit is needed as part of a hybrid circuit, connection must be made directly to the bond pads on the die. The chip can be attached to the substrate using an epoxy or by a gold/silicon eutectic bond. Once the chip is firmly held in position, wire bonding can commence. Three main methods are:

- Thermocompression;
- Ultrasonic;
- Thermosonic.

Thermocompression bonding relies on a combination of heat and pressure. The wire is usually made of gold with a diameter of around 25 μm . Gold or palladium/gold pads are deposited onto the hybrid substrate prior to bonding. The wire is fed through a ceramic capillary and a ball is formed at the end of the wire by a flame or spark discharge. A temperature of 350 $^{\circ}\text{C}$ is required for the bond and is achieved by heating either the substrate or the capillary. An epoxy chip bond cannot be used with this technique as it will soften during the bonding process. The first part of the bond is made on the aluminium bond pad on the chip; the capillary is lowered onto the pad and a force is applied to form a ball shape on the pad. The wire feeds out of the capillary and is then positioned over the desired pad on the substrate. As the capillary is lowered, a combination of heat and pressure forms the bond and the wire is then broken so that the process can be repeated for further bonds.

Ultrasonic bonding uses either a gold or aluminium wire and does not require external heat. The ultrasonic energy is supplied from a 40 kHz transducer. The combination of pressure and ultrasonic vibration causes the materials to bond together at the interface of the wire and the bond pad. This is generally a faster technique than the thermocompression method.

The final category, thermosonic bonding, is a combination of the other techniques. The substrate is heated to around 150 $^{\circ}\text{C}$ and the bond is made using the ultra-

sonic vibrations. This method is amenable to multilevel and multidirectional bonding and is therefore the preferred method, allowing bonding of up to 100 wires per minute.

30.4.5 Soldering of Surface-Mounted Components

Several techniques exist for the attachment of surface-mounted components to a thick film hybrid circuit. Surface-mounted components are generally much smaller than their through-hole counterparts. Of course, soldering by hand is also possible, although this is a tricky task requiring good operator skill and is often impractical because of the relatively long length of time needed.

Solder dipping requires the components to be placed on the board, either by hand or by a special pick-and-place machine. The components are fixed in position on the substrate by adding a small dot of glue and elevating the temperature to between 120 °C and 180 °C, which is sufficient to cure the adhesive. The board can then be dipped into a bath of molten solder at a temperature of 200 °C and then withdrawn at a sufficient rate to ensure that an adequate solder coating is obtained.

Wave soldering also requires the components to be fixed in position prior to the soldering process. Wave soldering machines were originally used for soldering through-hole components onto printed circuit boards, but they can also be used effectively with surface-mounted devices. The substrates are placed on a moving belt component side-down and initially pass through a flux bath before entering a solder bath. A wave of molten solder then flows over the substrate and creates a good joint at the desired location. This process can expose the components to a great thermal shock and it is therefore common to have a preheating phase which minimizes such effects. With both of these techniques, it is also necessary to ensure that a solder resist layer is applied to the substrate to cover all the areas that are not required to be soldered. With very densely populated circuits, there can also be a masking effect where some areas are not sufficiently coated with solder.

Reflow soldering is the preferred method of attaching surface-mounted devices. A solder cream is deposited onto the component pads either by screen printing or by a solder dispenser. The flux within the cream is sufficiently tacky to hold the component in place so that handling of the substrate is possible. After all of the components have been positioned on the circuit, the solder cream is dried and then reflowed.

This process takes place by belt reflow, vapor phase or infrared belt system. A typical belt reflow system comprises a thermally conducting belt upon which the substrates are placed. The belt then travels through a number of heating stages, which causes the solder cream to melt (reflow). Vapor-phase soldering requires the substrates to be lowered into a vessel containing a boiling, inert fluorocarbon. The vapor condenses onto the substrate and raises the temperature uniformly to that of the liquid below. Infrared belt reflow systems are similar to those used for drying thick film materials. The substrate is placed on a wire-mesh belt, which travels through several infrared radiator zones.

30.4.6 Packaging and Testing

Thick film hybrid circuits are very versatile and offer advantages over other forms of enabling technologies. Owing to this flexibility, the circuits have a wide range of shapes and sizes and hence there is no “standard” package type. Selection of a particular form of packaging must therefore involve the consideration of issues such as:

- Protection of the circuit from harsh environmental conditions;
- Protection from mechanical damage;
- Avoidance of water ingress;
- Electrical or mechanical connections to other parts of the system;
- Thermal mismatches of different materials.

A simple way of protecting the circuit is to screen print an overglaze layer over the substrate, covering all areas of the substrate except those where components are to be added. A lead frame can then be added to the substrate to allow external connections to be made. An example of a thick film hybrid circuit (without overglaze) is depicted

Fig. 30.11 A thick film hybrid circuit

in Fig. 30.11. The two resistors on the left of the circuit have been trimmed and the straight cuts are visible.

Conformal coatings are often used to protect the circuit from environmental attack. These are applied in the form of either a powder or fluid. In the former case, the substrate is heated and immersed into the powder. The temperature is then increased so that the coating dries. For fluids, the substrate is dipped into the coating material and subsequently dried at a temperature of around 70 °C. Typically, the thickness of a conformal coating is between 300 and 1200 μm.

For circuits requiring operation in harsh environments, a special hermetic packaging is needed. The package can be made from ceramics, metals, ceramic/metal or glass/ceramic compositions. The hermetic seal is made by brazing, welding or glass sealing

techniques. This form of packaging is often very expensive and is therefore only used in special application areas.

The final stage of the process is to test the circuit to see that its performance matches the design specification. Electrical testing can be difficult if the circuit has been coated or hermetically sealed, as physical access to components may be restricted. It is therefore usual to ensure that key test points are brought out to an external pin on the package. Environmental testing over a range of temperature and humidity may also be required in some circumstances. High-reliability circuits are often subject to a so-called burn-in phase, which involves holding the circuits at an elevated temperature for a given time to simulate the ageing process.

30.5 Sensors

Advances in the field of sensor development are greatly affected by the technologies that are used for their fabrication. The use of thick film processes as an enabling technology for modern-day sensors continues to expand. As we have already seen, the ability to produce miniaturized circuits is clearly one area in which thick film technology excels. The hybrid electronic circuitry can be integrated into the sensor housing to produce the basis of a smart (or intelligent) sensor [30.5]. Thick film technology also offers the advantage that it can provide a supporting structure onto which other materials can be deposited, possibly using other enabling technologies [30.6].

A major contribution of the technology to sensor development, however, results from the fact that the thick film itself can act as a primary sensing element. As an example, the thick film strain gauge, described below, is merely a conventional thick film resistor that is configured in such a way as to exploit one of its physical characteristics. Commercial thick film platinum conductors can be trimmed and used as calibrated temperature sensors. Most standard pastes, however, have not been specifically developed for sensor applications and do not necessarily have optimum sensing properties. The formulation of special-purpose thick film sensor pastes is the subject of intensive research activity [30.7].

For the purpose of this text, a *sensor* is considered as being a device that translates a signal from one of the common sensing domains (mechanical, thermal, op-

tical, chemical or magnetic) into an electrical signal. An *actuator* is a device that converts an electrical signal into one of the other domains (mainly mechanical).

30.5.1 Mechanical

In broad terms, thick film mechanical sensors are mainly based on piezoresistive, piezoelectric or capacitive techniques. Materials that exhibit a change in bulk resistivity when subjected to deformation by an external force are termed *piezoresistive*. A more common term is the strain gauge, denoting the fact that such devices produce a change in resistance when strained. The effect can be observed in standard cermet thick film resistors [30.6,8]. The sensitivity of a strain gauge is called the gauge factor and is defined as:

$$GF = \frac{\Delta R/R}{\varepsilon},$$

where $\Delta R/R$ is the relative change in resistance and ε is the applied strain (dimensionless). The gauge factors of metal foil strain gauges and thick film resistors are around 2 and 10 respectively. The former have typical resistance values of either 120 Ω or 350 Ω. As we have already seen, however, it is possible to produce thick film resistors with a wide range of resistance values, and this allows greater flexibility in strain gauge design. It is usual to place the strain gauges in a Wheatstone bridge configuration in order to produce a linear output analog voltage change that is proportional to the mechanical

measurand. A wide range of thick film piezoresistive sensors exist, including accelerometers, pressure sensors and load cells.

Piezoelectric materials exhibit the property of producing an electric charge when subjected to an applied mechanical force. They also deform in response to an externally applied electric field. This is an unusual effect, as the material can act as both a sensor and actuator. Certain crystals such as quartz and Rochelle salt are naturally occurring piezoelectrics, whilst others, like the ceramic materials barium titanate, lead zirconate titanate (PZT) and the polymer material polyvinylidene fluoride (PVDF), are *ferroelectric*. Ferroelectric materials are those that exhibit spontaneous polarization upon the application of an applied electric field. This means that ferroelectrics must be poled (polarized) prior to use in order to obtain piezoelectric behavior.

Thick film piezoelectrics have been made by mixing together PZT powder, a glass binder and an organic carrier [30.9]. A conducting layer is first screen printed, dried and fired onto a substrate and then several layers of the PZT film are deposited onto this lower electrode. The piezoelectric layer can be processed in a similar manner to conventional thick films. An upper electrode layer is then deposited onto the PZT in order to make a sandwich structure similar to that shown in Fig. 30.12. This is essentially a planar capacitor and the as-fired film must undergo a poling process by applying a DC electric field of around 4 MV/m and elevating the temperature to about 120 °C.

Thick film piezoelectrics have been used in a variety of sensor and actuator applications, including accelerometers, pressure sensors [30.10], micromachined pumps [30.11], surface acoustic wave (SAW) [30.12] and resonant sensors [30.13].

The capacitance C of a parallel plate capacitor is given by

$$C = \frac{\varepsilon_0 \varepsilon_r A}{d}$$

Fig. 30.12 Cross-section of a thick film piezoelectric sample

where ε_0 is the permittivity of free space, ε_r is the relative permittivity of the material between the electrodes, A is the area of overlap, and d is the separation of the electrodes. A mechanical sensor exhibiting a change in capacitance can be made by varying A , d or by displacing the dielectric (changing ε_r). The most popular configuration is to vary d in accordance with the desired measurand. This results in a nonlinear relationship between displacement and capacitance. If the variable plate is positioned between two fixed outer electrodes, then a differential structure with a linear response can be obtained. This is a common arrangement in many types of pressure sensor.

30.5.2 Thermal

Devices that exhibit a change in resistance in accordance with variations in temperature are termed *thermoresistive*. For metals, such devices have a linear response to temperature and are known as resistance thermometers. Thermally sensitive semiconductors, typically having a nonlinear response, are termed *thermistors*. Thick film platinum conductor layers can be used as resistance thermometers and exhibit a linear TCR of around 3800 ppm/°C, slightly lower than that of bulk platinum, which is around 4000 ppm/°C. Platinum resistance thermometers (PRTs) are often trimmed so that they have a resistance (R_0) of 100 Ω at 0 °C. Such sensors are sometimes referred to as Pt 100s and are often made of wound platinum wire. Thick film Pt 100s, fabricated onto alumina substrates, are available commercially and are considerably cheaper than the bulk versions. The following expression applies to a PRT over the linear part of the temperature characteristic (−200 °C to +500 °C)

$$R = R_0(1 + \alpha T),$$

where R is the resistance at a temperature T and α is the TCR (ppm/°C).

Thermistors are usually available in the form of discs, rods or beads comprising a sintered composite of a ceramic and a metallic oxide (typically manganese, copper or iron). Thermistor pastes are commercially available and screen-printed sensors are fabricated in a similar manner to conventional thick film resistors. The electrodes are first printed and fired onto an alumina substrate. The thermistor is then deposited across the electrodes and can be trimmed to a specific value if desired. Most thermistors have a negative temperature coefficient (NTC) of resistance; in other words their resistance decreases as the temperature increases. The

resistance versus temperature relationship is of the form

$$R = R_0 \exp \left[\beta \left(\frac{1}{T} - \frac{1}{T_0} \right) \right]$$

where R_0 is the resistance at a reference temperature T_0 (usually 25 °C).

Positive temperature coefficient (PTC) thermistors are also available, although they are generally not as stable or repeatable as NTCs and are therefore used as simple thermal detectors rather than calibrated devices.

Another type of temperature sensor can be made by joining together two dissimilar metals (or semiconductors). If a temperature difference exists between the joined and open ends, then an open-circuit voltage can be measured between the open ends. This is known as the Seebeck effect and is the basis of a *thermocouple*. A thick film version can be made by overlapping different conductor materials on a substrate, although the thermal sensitivity is much less than traditional wire-based devices.

30.5.3 Optical

Screen-printed photosensors are probably one of the earliest examples of thick film sensors, and their use dates back to the mid 1950s. Materials that exhibit a change in electrical conductivity due to absorbed electromagnetic radiation are known as *photoconductors*. Cadmium sulfide (CdS) is an example of such a material and is notable because of its highly sensitive response in the visible range (450–700 nm). The resistances of such devices can drop from several tens of MΩ in the dark to a few tens of ohms in bright sunlight.

Thick film photoconductor pastes are not widely available commercially, but have been the subject of some research activity [30.14]. Such pastes, based on cadmium sulfide and selenide, are prepared by sintering powdered CdS or CdSe with a small amount of cadmium chloride (which acts as a flux) at a temperature of around 600 °C. This is then ground into a powder and mixed with an organic carrier to make a screen-printable paste. This can then be printed over metal electrodes and fired at a temperature of around 600 °C in air.

30.5.4 Chemical

Thick film materials have been used in a variety of chemical sensor applications for the measurement of gas and liquid composition, acidity and humidity [30.15]. The two main techniques are impedance-based sensors and electrochemical sensors. With the former method, the

measurand causes a variation in resistance or capacitance, whilst the latter relies on the sensed quantity changing an electrochemical potential or current.

Impedance-based gas sensor pastes usually comprise a semiconducting metal oxide powder, inorganic additives and organic binders [30.16]. The paste is printed over metal electrodes and a back-heated resistor on an alumina substrate. The heating element is necessary to promote the reaction between the gas being measured and the sensing layer. Figure 30.13 shows an example of a thick film sensor, without a heating element, that can be used to measure humidity. The interlocking ‘finger’ electrodes are often referred to as interdigitated electrodes and are screen printed and fired onto an alumina substrate. A porous dielectric layer is then screen printed onto the electrodes. As the humidity increases, moisture will penetrate the surface of the dielectric layer causing a change in dielectric constant within the sensitive layer. This results in a change in capacitance between the electrodes.

Electrochemical techniques can be used to realise pH sensors. These are often used in biomedical, fermentation, process control and environmental applications. These devices often make use of a solid electrolyte which generates an electrochemical potential between two electrodes in response to the measurand.

Perhaps the most common example of a thick film chemical sensor is the disposable, polymer-based glucose sensor used in many home testing kits for diabetic patients. This illustrates how thick film sensors can offer robust, compact and cost-effective solutions to many modern-day requirements.

30.5.5 Magnetic

Some screen-printable conductors, particularly those containing nickel, exhibit a change in resistivity in response to an applied magnetic field. Such devices are referred to as *magnetoresistive* sensors. Air-fireable

Fig. 30.13 A thick film humidity sensor

nickel-based conductors have been shown to exhibit a nonlinear change in resistance for a linear increase in applied magnetic field [30.17]. A peak change in resistance of around 1% can occur at an applied field of 0.1 T. Researchers have made linear and rotary displacement sensors based on thick film nickel pastes, although it should be noted that such devices are also thermoresistive and therefore the magnetic measurements need to be taken in a temperature-controlled environment.

30.5.6 Actuators

We have previously defined an actuator as a device that converts a signal from the electrical domain into one of the other signal domains. It was noted earlier that piezoelectric materials produce a mechanical stress in

response to an electrical charge. Such materials can therefore be used as actuators. Thick film piezoelectric layers have been screen printed onto thin silicon diaphragms in order to form the basis of a micropump [30.11].

Photovoltaic devices convert incident optical radiation into electric current and are often termed *solar cells*. They are used to power devices such as calculators, clocks, pumps and lighting. In general terms, the output power level is proportional to the physical size of the photovoltaic cell. The device is essentially a heterojunction between n-type and p-type semiconductors. Thick film solar cells have been made comprising CdS (n-type) and CdTe (p-type) as the junction materials [30.18]. Such thick film actuators have been shown to have relatively low conversion efficiencies (between 1% and 10%).

31. III–V Ternary and Quaternary Compounds

III–V ternary and quaternary alloy systems are potentially of great importance for many high-speed electronic and optoelectronic devices, because they provide a natural means of tuning the magnitude of forbidden gaps so as to optimize and widen the applications of such semiconductor devices. Literature on the fundamental properties of these material systems is growing rapidly. Even though the basic semiconductor alloy concepts are understood at this time, some practical and device parameters in these material systems have been hampered by a lack of definite knowledge of many material parameters and properties.

This chapter attempts to summarize, in graphical and tabular forms, most of the important theoretical and experimental data on the III–V ternary and quaternary alloy parameters and properties. They can be classified into six groups: (1) Structural parameters; (2) Mechanical, elastic, and lattice vibronic properties; (3) Thermal properties; (4) Energy band parameters; (5) Optical properties, and; (6) Carrier transport properties. The III–V ternary and quaternary alloys considered here are those of Group III (Al, Ga, In) and V (N, P, As, Sb) atoms. The model used in some cases is based on an interpolation scheme and, therefore, requires that data on the material parameters for the related binaries (AlN, AlP, GaN, GaP, etc.) are known. These data have been taken mainly from the Landolt–Börnstein collection, Vol. III/41, and from the *Handbook on Physical Properties of Semiconductors Volume 2: III–V Compound Semiconductors*, published by Springer in 2004. The material parameters and properties derived

here are used with wide success to obtain the general properties of these alloy semiconductors.

31.1 Introduction to III–V Ternary and Quaternary Compounds

III–V semiconducting compound alloys are widely used as materials for optoelectronic devices such as light-emitting diodes, laser diodes and photodetectors, as well as for electronic transport devices such as field effect transistors, high electron mobility transistors and het-

erojunction bipolar transistors. In a ternary alloy, the bandgap energy E_g and the lattice parameter a are generally both functions of a single composition parameter, so they cannot be selected independently. In quaternary alloys, on the other hand, the two com-

position parameters allow E_g and a to be selected independently, within the constraints of a given alloy–substrate system. Even though the basic semiconductor alloy concepts are understood at this time, the determination of some practical device parameters has been hampered by a lack of definite knowledge of many material parameters. This chapter provides data on the fundamental material properties of III–V ternary and quaternary alloys. The model used here is based on an interpolation scheme and thus requires that

values of the material parameters for the related end-point binaries are known. We therefore begin with the constituent binaries and gradually move on to alloys. The phenomenon of spontaneous ordering in semiconductor alloys, which can be categorized as a self-organized process, is observed to occur spontaneously during the epitaxial growth of certain alloys, and results in modifications to their structural, electronic and optical properties. This topic is omitted from the coverage [31.1].

31.2 Interpolation Scheme

The electronic energy band parameters of III–V compound alloys and their dependence on alloy composition are very important device parameters, and so they have received considerable attention in the past. Investigations of many device parameters have, however, been hampered by a lack of definite knowledge of various material parameters. This necessitates the use of some kind of interpolation scheme. Although the interpolation scheme is still open to experimental verification, it can provide more useful and reliable material parameters over the entire range of alloy composition [31.2].

If one uses the linear interpolation scheme, the ternary parameter T can be derived from the binary parameters (B) by

$$T_{A_xB_{1-x}C} = xB_{AC} + (1-x)B_{BC} \equiv a + bx \quad (31.1)$$

for an alloy of the form $A_xB_{1-x}C$, where $a \equiv B_{BC}$ and $b \equiv B_{AC} - B_{BC}$. Some material parameters, however, deviate significantly from the linear relation (31.1), and exhibit an approximately quadratic dependence on the mole fraction x . The ternary material parameter in such a case can be very efficiently approximated by the relationship

$$T_{A_xB_{1-x}C} = xB_{AC} + (1-x)B_{BC} + C_{A-B}x(1-x) \equiv a + bx + cx^2, \quad (31.2)$$

where $a \equiv B_{BC}$ and $b \equiv B_{AC} - B_{BC} + C_{A-B}$, and $c \equiv -C_{A-B}$. The parameter c is called the bowing or nonlinear parameter.

The quaternary material $A_xB_{1-x}C_yD_{1-y}$ is thought to be constructed from four binaries: AC, AD, BC, and BD. If one uses the linear interpolation scheme, the quaternary parameter Q can be derived from the B s by

$$Q(x, y) = xyB_{AC} + x(1-y)B_{AD} + (1-x)yB_{BC} + (1-x)(1-y)B_{BD}. \quad (31.3)$$

If one of the four binary parameters (e.g., B_{AD}) is lacking, Q can be estimated from

$$Q(x, y) = xB_{AC} + (y-x)B_{BC} + (1-y)B_{BD}. \quad (31.4)$$

The quaternary material $A_xB_yC_{1-x-y}D$ is thought to be constructed from three binaries: AD, BD, and CD. The corresponding linear interpolation is given by

$$Q(x, y) = xB_{AD} + yB_{BD} + (1-x-y)B_{CD}. \quad (31.5)$$

If the material parameter can be given by a specific expression owing to some physical basis, it is natural to consider that the interpolation scheme may also obey this expression. The static dielectric constant ϵ_s is just the case that follows the Clausius–Mosotti relation. Then, the interpolation expression for the $A_xB_{1-x}C_yD_{1-y}$ quaternary, for example, has the form

$$\begin{aligned} \frac{\epsilon_s(x, y) - 1}{\epsilon_s(x, y) - 2} = & xy \frac{\epsilon_s(AC) - 1}{\epsilon_s(AC) - 2} + x(1-y) \frac{\epsilon_s(AD) - 1}{\epsilon_s(AD) - 2} \\ & + (1-x)y \frac{\epsilon_s(BC) - 1}{\epsilon_s(BC) - 2} \\ & + (1-x)(1-y) \frac{\epsilon_s(BD) - 1}{\epsilon_s(BD) - 2}. \end{aligned} \quad (31.6)$$

When bowing from the anion sublattice disorder is independent of the disorder in the cation sublattice, the interpolation scheme is written by incorporating these cation and anion bowing parameters into the linear interpolation scheme as

$$\begin{aligned} Q(x, y) = & xyB_{AC} + x(1-y)B_{AD} + (1-x)yB_{BC} \\ & + (1-x)(1-y)B_{BD} + C_{A-B}x(1-x) \\ & + C_{C-D}y(1-y) \end{aligned} \quad (31.7)$$

for the $A_xB_{1-x}C_yD_{1-y}$ quaternary, or

$$\begin{aligned} Q(x, y) = & xB_{AD} + yB_{BD} + (1-x-y)B_{CD} \\ & + C_{A-B} - C_{xy}(1-x-y) \end{aligned} \quad (31.8)$$

for the $A_xB_yC_{1-x-y}D$ quaternary.

If relationships for the ternary parameters T s are available, the quaternary parameter Q can be expressed either as $(A_xB_{1-x}C_yD_{1-y})$

$$Q(x, y) = \frac{x(1-x)[yT_{ABC}(x) + (1-y)T_{ABD}(x)]}{x(1-x) + y(1-y)} + \frac{y(1-y)[xT_{ACD}(y) + (1-x)T_{BCD}(y)]}{x(1-x) + y(1-y)}, \quad (31.9)$$

or $(A_xB_yC_{1-x-y}D)$

$$Q(x, y) = \frac{xyT_{ABD}(u) + y(1-x-y)T_{BCD}(v)}{xy + y(1-x-y) + x(1-x-y)} + \frac{x(1-x-y)T_{ACD}(w)}{xy + y(1-x-y) + x(1-x-y)} \quad (31.10)$$

with

$$u = (1-x-y)/2, \quad v = (2-x-2y)/2, \quad w = (2-2x-y)/2. \quad (31.11)$$

31.3 Structural Parameters

31.3.1 Lattice Parameters and Lattice-Matching Conditions Between III–V Quaternaries and Binary Substrates

The lattice parameter a (c) is known to obey Vegard's law well, i. e., to vary linearly with composition. Thus, the lattice parameter for a III–V ternary can be simply obtained from (31.1) using the binary data

Table 31.1 Lattice parameters a and c and crystal density g for some III–V binaries at 300 K

Binary	Zinc blende a (Å)	Wurtzite a (Å)	c (Å)	g (g/cm ³)
AlN	–	3.112	4.982	3.258
AlP	5.4635	–	–	2.3604
AlAs	5.661 39	–	–	3.7302
AlSb	6.1355	–	–	4.2775
α -GaN	–	3.1896	5.1855	6.0865
β -GaN	4.52	–	–	6.02
GaP	5.4508	–	–	4.1299
GaAs	5.653 30	–	–	5.3175
GaSb	6.095 93	–	–	5.6146
InN	–	3.548	5.760	6.813
InP	5.8690	–	–	4.7902
InAs	6.0583	–	–	5.6678
InSb	6.479 37	–	–	5.7768

listed in Table 31.1 [31.3, 4]. Introducing the lattice parameters in Table 31.1 into (31.3) [(31.5)], one can also obtain the lattice-matching conditions for $A_{1-x}B_xC_yD_{1-y}$ ($A_xB_yC_{1-x-y}D$) quaternaries on various III–V binary substrates (GaAs, GaSb, InP and InAs). These results are summarized in Tables 31.2, 31.3, 31.4 and 31.5.

31.3.2 Molecular and Crystal Densities

The molecular density d_M can be obtained via

$$d_M = \frac{4}{a^3} \quad (31.12)$$

for zinc blende-type materials, and

$$d_M = \frac{4}{a_{\text{eff}}^3} \quad (31.13)$$

for wurtzite-type materials, where a_{eff} is an effective cubic lattice parameter defined by

$$a_{\text{eff}} = (\sqrt{3}a^2c)^{1/3}. \quad (31.14)$$

The X-ray crystal density g can be simply written, using d_M , as

$$g = \frac{Md_M}{N_A}, \quad (31.15)$$

Table 31.2 Lattice-matching conditions for some III–V quaternaries of type $A_xB_{1-x}C_yD_{1-y}$ at 300 K. $x = \frac{A_0+B_0y}{C_0+D_0y}$

Quaternary	Substrate	A_0	B_0	C_0	D_0	Remark

31.4 Mechanical, Elastic and Lattice Vibronic Properties

31.4.1 Microhardness

The hardness test has been used for a long time as a simple means of characterizing the mechanical behavior of solids. The Knoop hardness H_P for $\text{Ga}_x\text{In}_{1-x}\text{P}_y\text{As}_{1-y}$ lattice-matched to InP has been reported [31.5], and is found to increase gradually from 520 kg/mm² for $y = 0$ ($\text{Ga}_{0.47}\text{In}_{0.53}\text{As}$) to 380 kg/mm² for $y = 1.0$ (InP). It has also been reported that the microhardness in $\text{Al}_x\text{Ga}_{1-x}\text{N}$ thin film slightly decreases with increasing AlN composition x [31.6].

31.4.2 Elastic Constants and Related Moduli

Although the elastic properties of the III–V binaries have been studied extensively, little is known about their alloys. Recent studies, however, suggested that the elastic properties of the alloys can be obtained, to a good approximation, by averaging the binary endpoint values [31.7, 8]. We have, therefore, listed in Tables 31.6 and 31.7 the elastic stiffness (C_{ij}) and compliance constants (S_{ij}) for some III–V binaries with zinc blende and wurtzite structures, respectively. Table 31.8 also sum-

marizes the functional expressions for the bulk modulus B_u , Young's modulus Y , and Poisson's ratio P . Note that Y and P are not isotropic, even in the cubic zinc blende lattice.

31.4.3 Long-Wavelength Phonons

The atoms of a crystal can be visualized as being joined by harmonic springs, and the crystal dynamics can be analyzed in terms of a linear combination of $3N$ normal modes of vibration (N is the number of different types of atoms; different in terms of mass or ordering in space). In alloys, the nature of the lattice optical spectrum depends on the difference between the quantities representing the lattice vibronic properties of the components. If these quantities are similar, then the optical response of an alloy is similar to the response of a crystal with the quantities averaged over the composition (one-mode behavior). In one-mode systems, such as most I–VII alloys, a single set of long-wavelength optical modes appears, as schematically shown in Fig. 31.1. When the parameters differ strongly, the response of a system is more complex; the spectrum contains a num-

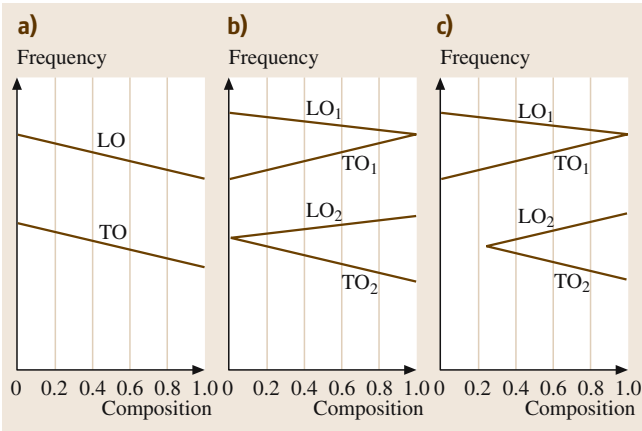

Fig. 31.1a–c Three different types of long-wavelength phonon mode behavior in ternary alloys: (a) one-mode; (b) two-mode; and (c) one-two-mode ◀

cal modes with frequencies characteristic of each end member and strengths that are roughly proportional to the respective concentrations.

As seen in Table 31.9, the long-wavelength optical phonons in III–V ternaries exhibit either one-mode or two-mode behavior, or more rigorously, three different types of mode behavior: one-mode, two-mode, and one-two-mode behaviors. The one-two-mode system exhibits a single mode over only a part of the composition range, with two modes observed over the remaining range of compositions.

In a quaternary alloy of the $A_xB_{1-x}C_yD_{1-y}$ type, there are four kinds of unit cells: AC, AD, BC, and BD. On the other hand, in the $A_xB_yC_{1-x-y}D$ type there are three kinds of unit cells: AD, BD, and CD. We can, thus, expect four-mode or three-

Table 31.9 Behavior of the long-wavelength optical modes in III–V ternary and quaternary alloys

Four mode	GaIn PSb , GaIn PAs

mode behavior of the long-wavelength optical modes in such quaternary alloys ([31.9]; Table 31.9). However, the $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{Sb}_{1-y}$ quaternary showed three-mode behavior with GaAs, InSb and mixed InAs/GaAs characteristics [31.10]. The $\text{Ga}_x\text{In}_{1-x}\text{As}_y\text{Sb}_{1-y}$ quaternary was also reported to show two-mode or three-mode behavior, depending on the alloy composition [31.11].

The long-wavelength optical phonon behavior in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ ternary has been studied both theoretically and experimentally. These studies suggest that the optical phonons in $\text{Al}_x\text{Ga}_{1-x}\text{As}$ exhibit the two-mode behavior over the whole composition range. Thus, the

$\text{Al}_x\text{Ga}_{1-x}\text{As}$ system has two couples of the transverse optical (TO) and longitudinal optical (LO) modes; one is the GaAs-like mode and the other is the AlAs-like mode. Each phonon frequency can be expressed as [31.12]

- TO (GaAs): $268 - 14x \text{ cm}^{-1}$,
- LO (GaAs): $292 - 38x \text{ cm}^{-1}$,
- TO (AlAs): $358 + 4x \text{ cm}^{-1}$,
- LO (AlAs): $358 + 71x - 26x^2 \text{ cm}^{-1}$.

It is observed that only the AlAs-like LO mode shows a weak nonlinearity with respect to the alloy composition x .

31.5 Thermal Properties

31.5.1 Specific Heat and Debye Temperature

Since alloying has no significant effect on elastic properties, it appears that using the linear interpolation scheme for alloys can provide generally acceptable specific heat values (C). In fact, it has been reported that the C values for $\text{InP}_x\text{As}_{1-x}$ [31.13] and $\text{Al}_x\text{Ga}_{1-x}\text{As}$ [31.14] vary fairly linearly with alloy composition x . It has also been shown [31.12] that the Debye temperature θ_D for alloys shows very weak nonlinearity with composition. From these facts, one can suppose that the linear interpolation scheme may provide generally acceptable C and θ_D values for III-V semiconductor alloys. We have, therefore, listed in Table 31.10 the III-V binary endpoint

values for C and θ_D at $T = 300 \text{ K}$. Using these values, the linearly interpolated C value for $\text{Al}_x\text{Ga}_{1-x}\text{As}$ can be obtained from $C(x) = 0.424x + 0.327(1-x) = 0.327 + 0.097x \text{ (J/gK)}$.

31.5.2 Thermal Expansion Coefficient

The linear thermal expansion coefficient α_{th} is usually measured by measuring the temperature dependence of the lattice parameter. The composition dependence of α_{th} has been measured for many semiconductor alloys, including $\text{Ga}_x\text{In}_{1-x}\text{P}$ [31.15] and $\text{GaP}_x\text{As}_{1-x}$ [31.16]. These studies indicate that the α_{th} value varies almost linearly with composition. This suggests that the thermal expansion coefficient can be accurately estimated using linear interpolation. In fact, we plot in Fig. 31.2 the 300 K value of α_{th} as a function of x for the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ ternary. By using the least-squares fit procedure, we obtain the linear relationship between α_{th} and x as $\alpha_{\text{th}}(x) = 6.01 - 1.74x \text{ (} 10^{-6} \text{ K}^{-1} \text{)}$. This expression is almost the same as that obtained using the linear interpolation expression: $\alpha_{\text{th}}(x) = 4.28x + 6.03(1-x) = 6.03 - 1.75x \text{ (} 10^{-6} \text{ K}^{-1} \text{)}$. The binary endpoint values of α_{th} are listed in Table 31.10.

31.5.3 Thermal Conductivity

The lattice thermal conductivity κ , or the thermal resistivity $W = 1/\kappa$, results mainly from interactions between phonons and from the scattering of phonons by crystalline imperfections. It is important to point out that when large numbers of foreign atoms are added to the host lattice, as in alloying, the thermal conductivity may

ear parameters C_{A-B} are also listed in Table 31.11. The agreement between the calculated and experimental data is excellent. By applying the present model, it is possi-

ble to estimate the κ (or W) values of experimentally unknown III–V alloy systems, such as $\text{GaAs}_x\text{Sb}_{1-x}$ and $\text{Al}_x\text{Ga}_y\text{In}_{1-x-y}\text{As}$.

31.6 Energy Band Parameters

31.6.1 Bandgap Energy

Lowest Direct and Lowest Indirect Band Gaps

The bandgap energies of III–V ternaries usually deviate from the simple linear relation of (31.1) and have an approximately quadratic dependence on the alloy composition x . Table 31.12 summarizes the lowest direct gap energy E_0 and the lowest indirect gap energies E_g^X and E_g^L for some III–V binaries of interest here. The corresponding nonlinear parameters C_{A-B} are listed in Table 31.13 [31.18]. Note that the E_g^X and E_g^L transitions correspond to those from the highest valence band at the Γ point to the lowest conduction band near X ($\Gamma_8 \rightarrow X_6$) or near L ($\Gamma_8 \rightarrow L_6$), respectively. The E_0 transitions take place at the Γ point ($\Gamma_8 \rightarrow \Gamma_6$).

Figure 31.4 plots the values of E_0 and E_g^X as a function of alloy composition x for the $\text{Ga}_x\text{In}_{1-x}\text{P}$ ternary at $T = 300\text{ K}$. The solid lines are obtained by introducing the numerical values from Tables 31.12 and 31.13 into (31.2). These curves provide the direct-indirect crossover composition at $x \approx 0.7$. Figure 31.5 also shows the variation in composition of E_0 in the

* In those case where no value is listed, linear variation should be assumed

Fig. 31.4 Variation of the lowest direct gap (E_0) and lowest indirect gap energies (E_g^X) in the $\text{Ga}_x\text{In}_{1-x}\text{P}$ ternary at $T = 300$ K. The experimental data are gathered from various sources. The solid lines are calculated from (31.2) using the binary endpoint values and bowing parameters in Tables 31.12 and 31.13

Higher-Lying Band Gaps

The important optical transition energies observed at energies higher than E_0 are labeled E_1 and E_2 . We summarize in Table 31.15 the higher-lying bandgap energies E_1 and E_2 for some III–V binaries. The corresponding bowing parameters for these gaps are listed in Table 31.16.

31.6.2 Carrier Effective Mass

Electron Effective Mass

Since the carrier effective mass is strongly connected with the carrier mobility, it is known to be one of the most important device parameters. Effective masses can be measured by a variety of techniques, such as the Shubnikov-de Haas effect, magnetophonon resonance, cyclotron resonance, and interband magneto-optical effects. We list in Table 31.17 the electron effective mass (m_e^Γ) at the Γ -conduction band and the density of states (m_e^σ) and conductivity masses (m_e^σ) at the X-conduction and L-conduction bands of some III–V binaries. We also list in Table 31.18 the bowing parameters used when calculating the electron effective mass m_e^Γ for some III–V

tal uncertainty (Figs. 31.4, 31.5). It should be noted that nitrogen incorporation into (In,Ga)(P,As) results in a giant bandgap bowing of the host lattice for increasing nitrogen concentration [31.19]. We also summarize in Table 31.14 the expressions for the E_0 gap energy of some III–V quaternaries as a function of alloy composition.

Fig. 31.5 Variation of the lowest direct gap energy E_0 ($T = 300$ K) and electron effective mass m_e^Γ at the Γ -conduction bands of $\text{Ga}_x\text{In}_{1-x}\text{As}$, $\text{InAs}_x\text{Sb}_{1-x}$ and $\text{Ga}_x\text{In}_{1-x}\text{Sb}$ ternaries. The experimental data are gathered from various sources. The solid lines are calculated from (31.2) using the binary endpoint values and bowing parameters in Tables 31.12 and 31.13 (E_0) and those in Tables 31.17 and 31.18 (m_e^Γ)

Table 31.14 Bandgap energies E_0 for some III–V quaternaries at 300 K

ternaries from (31.2). Note that the density of states mass m_e^α for electrons in the conduction band minima $\alpha = \Gamma$, X, and L can be obtained from

$$m_e^\alpha = N^{2/3} m_{t\alpha}^{2/3} m_{l\alpha}^{1/3}, \quad (31.16)$$

where N is the number of equivalent α minima ($N = 1$ for the Γ minimum, $N = 3$ for the X minima, and $N = 4$ for the L minima). The two masses m_l and m_t in (31.16) are called the longitudinal and transverse masses, respectively. The density of states effective mass m_e^α is used to calculate the density of states. The conductivity effective mass m_c^α , which can be used for calculating the conductivity (mobility), is also given by

$$m_c^\alpha = \frac{3m_{t\alpha}m_{l\alpha}}{m_{t\alpha} + 2m_{l\alpha}}. \quad (31.17)$$

Since $m_{t\Gamma} = m_{l\Gamma}$ at the $\alpha = \Gamma$ minimum of cubic semiconductors, we have the relation $m_c^\Gamma = m_l^\Gamma$. In the case of wurtzite semiconductors, we have the relation $m_c^\Gamma \neq m_l^\Gamma$, but the difference is very small.

Table 31.16 Bowing parameters used in the calculation of the higher-lying bandgap energies, E_1 and E_2 , for some cubic III–V ternaries

* In those cases where no value is listed, linear variation should be assumed

The composition dependence of the electron effective mass m_e^Γ at the Γ -conduction bands of $\text{Ga}_x\text{In}_{1-x}\text{As}$, $\text{InAs}_x\text{Sb}_{1-x}$ and $\text{Ga}_x\text{In}_{1-x}\text{Sb}$ ternaries is plotted in Fig. 31.5. The solid lines are calculated from (31.2) using the binary endpoint values and bowing parameters in Tables 31.17 and 31.18. For conventional semiconductors, the values of the effective mass are known to decrease with decreasing bandgap energy (Fig. 31.5). This is in agreement with a trend predicted by the $\mathbf{k} \cdot \mathbf{p}$ theory [31.2]. In III–V–N alloys, the electron effective mass has been predicted to increase with increasing nitrogen composition in the low composition range [31.19]. This behavior is rather unusual, and in fact is opposite to what is seen in conventional semiconductors. However, a more recent study suggested that the effective electron mass in $\text{GaN}_x\text{As}_{1-x}$ decreases from $0.084m_0$ to $0.029m_0$ as x increases from 0 to 0.004 [31.20]. We also summarize in Table 31.19 the composition dependence of m_e^Γ , determined for $\text{Ga}_x\text{In}_{1-x}\text{P}_y\text{As}_{1-y}$ and $\text{Al}_x\text{Ga}_y\text{In}_{1-x-y}\text{As}$ quaternaries lattice-matched to InP.

Hole Effective Mass

The effective mass can only be clearly defined for an isotropic parabolic band. In the case of III–V materials, the valence bands are warped from spherical symmetry some distance away from the Brillouin zone center

Table 31.17 Electron effective mass at the Γ -conduction band (m_e^Γ) and density of states (m_e^α) and conductivity masses (m_e^α) at the X-conduction and L-conduction bands of some III–V binaries. ZB = zinc blende

Quaternary	m_e^Γ/m_0
$\text{Ga}_x\text{In}_{1-x}\text{P}_y\text{As}_{1-y}/\text{InP}$	$0.043 + 0.036y$
$\text{Al}_x\text{Ga}_y\text{In}_{1-x-y}\text{As}/\text{InP}$	$0.043 + 0.046x - 0.017x^2$

(Γ). Depending on the measurement or calculation technique employed, different values of hole masses are then possible experimentally or theoretically. Thus, it is always important to choose the correct definition of the effective hole mass which appropriate to the physical phenomenon considered.

We list in Table 31.20 the density of states heavy hole (m_{HH}^*), the averaged light hole (m_{LH}^*), and spin orbit splitoff effective hole masses (m_{SO}) in some cubic

III–V semiconductors. These masses are, respectively, defined using Luttinger’s valence band parameters γ_i by

$$m_{\text{HH}}^* = \frac{(1 + 0.05\gamma_h + 0.0164\gamma_h^2)^{2/3}}{\gamma_1 - \bar{\gamma}}, \quad (31.18)$$

$$m_{\text{LH}}^* = \frac{1}{\gamma_1 + \bar{\gamma}}, \quad (31.19)$$

$$m_{\text{SO}} = \frac{1}{\gamma_1} \quad (31.20)$$

with

$$\bar{\gamma} = (2\gamma_2^2 + 2\gamma_3^2)^{1/2}, \quad \gamma_h = \frac{6(\gamma_3^2 - \gamma_2^2)}{\bar{\gamma}(\gamma_1 - \bar{\gamma})}. \quad (31.21)$$

Only a few experimental studies have been performed on the effective hole masses in III–V alloys, e.g., the $\text{Ga}_x\text{In}_{1-x}\text{P}_y\text{As}_{1-y}$ quaternary [31.2]. While some data imply a bowing parameter, the large uncertainties in existing determinations make it difficult to conclusively state that such experimental values are preferable to a linear interpolation. The binary endpoint data listed in Table 31.20 enable us to estimate alloy values using the linear interpolation scheme.

31.6.3 Deformation Potential

The deformation potentials of the electronic states at the Brillouin zone centers of semiconductors play an important role in many physical phenomena. For example,

Table 31.20 Density of states heavy hole (m_{HH}^*), averaged light hole (m_{LH}^*), and spin orbit splitoff effective hole masses (m_{SO}) in some cubic III–V semiconductors. ZB = zinc blende

the splitting of the heavy hole and light hole bands at the Γ point of the strained substance can be explained by the shear deformation potentials, b and d . The lattice mobilities of holes are also strongly affected by these potentials. Several experimental data have been reported on the deformation potential values for III–V alloys, e.g., $\text{Al}_x\text{Ga}_{1-x}\text{As}$ [31.12], $\text{GaP}_x\text{As}_{1-x}$ [31.21] and $\text{Al}_x\text{In}_{1-x}\text{As}$ [31.22]. Due to the large scatter in the experimental binary endpoint values, it is very difficult to establish any evolution of the deformation potentials with composition. We list in Table 31.21 the recommended values for the conduction band (a_c) and valence band deformation potentials (a_v , b , d) of some cubic III–V binaries. The deformation potentials for some wurtzite III–V semiconductors are also collected in Table 31.22. Until more precise data become available, we suggest employing the linear interpolation expressions in order to estimate the parameter values of these poorly explored properties.

31.7 Optical Properties

31.7.1 The Reststrahlen Region

It should be noted that in homopolar semiconductors like Si and Ge, the fundamental vibration has no dipole moment and is infrared inactive. In heteropolar semiconductors, such as GaAs and InP, the first-order dipole moment gives rise to a very strong absorption band associated with optical modes that have a k vector of essentially zero (i.e., long-wavelength optical phonons). This band is called the reststrahlen band. Below this band, the real part of the dielectric constant asymptotically approaches the static or low-frequency dielectric constant ϵ_s . The optical constant connecting the reststrahlen near-infrared spectral range is called the high-frequency or optical dielectric constant ϵ_∞ . The value of ϵ_∞ is, therefore, measured for frequencies well above the long-wavelength LO phonon frequency but below the fundamental absorption edge.

Fig. 31.6 High-frequency dielectric constant ϵ_∞ as a function of x for the $\text{Al}_x\text{Ga}_{1-x}\text{Sb}$ ternary. The experimental data are taken from Lucovsky et al. [31.23] (solid circles), Ance and Mau [31.24] (open circles), and Ferrini et al. [31.25] (open triangles). The solid and dashed lines are, respectively, calculated from (31.1) and (31.6) (ternary) with the binary endpoint values in Table 31.23

Table 31.23 Static (ϵ_s) and high-frequency dielectric constants (ϵ_∞) for some cubic III–V binaries. ZB = zinc blende

InAs	14.3	11.6
InSb	17.2	15.3

* Calculated or estimated

Table 31.24 Static (ϵ_s) and high-frequency dielectric constants (ϵ_∞) for some wurtzite III–V binaries

Binary	$E \perp c$		$E \parallel c$	
	ϵ_s	ϵ_∞	ϵ_s	ϵ_∞
AlN	8.3	4.4	8.9	4.8
α -GaN	9.6	5.4	10.6	5.4
InN	13.1*	8.4*	14.4*	8.4*

* Estimated

The general properties of ϵ_s and ϵ_∞ for a specific family of compounds, namely III–V and II–VI compounds, suggest that the dielectric constants in alloy semiconductors could be deduced by using the linear interpolation method [31.26]. The simplest linear interpolation method is to use (31.1), (31.3) or (31.5). The linear interpolation scheme based on the Clausius–Mosotti relation can also be obtained from (31.6). In Fig. 31.6, we show the interpolated ϵ_∞ as a function of x for the $\text{Al}_x\text{Ga}_{1-x}\text{Sb}$ ternary. The solid and dashed lines are, respectively, calculated from (31.1) and (31.6) (ternary). The experimental data are taken from Lucovsky et al. [31.23], Ance and Mau [31.24], and Ferrini et al. [31.25]. The binary endpoint values used in the calculation are listed in Table 31.23. These two methods are found to provide almost the same interpolated values. Table 31.24 also lists the ϵ_s and ϵ_∞ values for some wurtzite III–V binary semiconductors.

The optical spectra observed in the reststrahlen region of alloy semiconductors can be explained by the

following multioscillator model [31.12]:

$$\varepsilon(\omega) = \varepsilon_\infty + \sum_j \frac{S_j \omega_{\text{TO}j}^2}{\omega_{\text{TO}j}^2 - \omega^2 - i\omega\gamma_j}, \quad (31.22)$$

Fig. 31.7 $\varepsilon(\omega)$ spectra in the reststrahlen region of the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ ternary

where $S_j = \varepsilon_\infty (\omega_{\text{LO}j}^2 - \omega_{\text{TO}j}^2)$ is the oscillator strength, $\omega_{\text{TO}j}$ ($\omega_{\text{LO}j}$) is the **TO** (**LO**) phonon frequency, and γ_j is the damping constant of the j -th lattice oscillator. We show in Fig. 31.7, as an example, the optical spectra in the reststrahlen region of the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ ternary. As expected from the two-mode behavior of the long-wavelength optical phonons, the $\varepsilon(\omega)$ spectra of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ exhibit two main optical resonances: GaAs-like and AlAs-like.

31.7.2 The Interband Transition Region

The optical constants in the interband transition regions of semiconductors depend fundamentally on the electronic energy band structure of the semiconductors. The relation between the electronic energy band structure and $\varepsilon_2(E)$ is given by

$$\varepsilon_2(E) = \frac{4e^2\hbar^2}{\pi\mu^2E^2} \int d\mathbf{k} |P_{cv}(\mathbf{k})|^2 \delta[E_c(\mathbf{k}) - E_v(\mathbf{k}) - E], \quad (31.23)$$

where μ is the combined density of states mass, the Dirac δ function represents the spectral joint density of states between the valence-band [$E_v(\mathbf{k})$] and conduction-band states [$E_c(\mathbf{k})$], differing by the energy $E = \hbar\omega$ of the incident light, $P_{cv}(\mathbf{k})$ is the momentum matrix element between the valence-band and conduction-band states, and the integration is performed over the first Brillouin zone. The Kramers–Kronig relations link $\varepsilon_2(E)$ and $\varepsilon_1(E)$ in a manner that means that $\varepsilon_1(E)$ can be calculated at each photon energy if $\varepsilon_2(E)$ is known explicitly over the entire photon energy

Fig. 31.8 $\varepsilon(E)$ spectra for $\text{Al}_x\text{Ga}_y\text{In}_{1-x-y}\text{P}/\text{GaAs}$ at room temperature. The experimental data are taken from Adachi [31.27]; open and solid circles. The solid lines represent the theoretical fits for the MDF calculation

range, and vice versa. The Kramers–Kronig relations are of fundamental importance in the analysis of optical spectra [31.9].

The refractive indices and absorption coefficients of semiconductors are the basis of many important applications of semiconductors, such as light-emitting diodes, laser diodes and photodetectors. The optical constants of III–V binaries and their ternary and quaternary alloys have been presented in tabular and graphical forms [31.27]. We plot in Fig. 31.8 the $\varepsilon(E)$ spectra for $\text{Al}_x\text{Ga}_y\text{In}_{1-x-y}\text{P}/\text{GaAs}$ taken from tabulation by

Adachi [31.27]; open and solid circles). The solid lines represent the theoretical fits of the model dielectric function (MDF) calculation [31.9]. The three major features of the spectra seen in Fig. 31.8 are the E_0 , E_1 and E_2 structures at ≈ 2 , ≈ 3.5 and ≈ 4.5 eV, respectively. It is found that the E_0 and E_1 structures move to higher energies with increasing x , while the E_2 structure does not do so to any perceptible degree. We can see that the MDF calculation enables us to calculate the optical spectra for optional compositions of alloy semiconductors with good accuracy.

31.8 Carrier Transport Properties

An accurate comparison between experimental mobility and theoretical calculation is of great importance for the determination of a variety of fundamental material parameters and carrier scattering mechanisms. There are various carrier scattering mechanisms in semiconductors, as schematically shown in Fig. 31.9. The effect of the individual scattering mechanisms on the total calculated carrier mobility can be visualized using Matthiessen’s rule:

1/μ_tot = Σ_i 1/μ_i . (31.24)

The total carrier mobility μ_{tot} can then be obtained from the scattering-limited mobilities μ_i of each scattering mechanism. We note that in alloy semiconductors the charged carriers see potential fluctuations as a result of

the composition disorder. This kind of scattering mechanism, so-called alloy scattering, is important in some III–V ternaries and quaternaries. The alloy scattering limited mobility in ternary alloys can be formulated as

μ_al = (√2πeħ^4 N_al α) / (3(m_c^*)^5/2 (kT)^1/2 x(1-x)(ΔU)^2) , (31.25)

where N_{al} is the density of alloy sites, m_c^* is the electron or hole conductivity mass, x and $(1-x)$ are the mole fractions of the binary endpoint materials, and ΔU is the alloy scattering potential. The factor α is caused by the band degeneracy and is given by $\alpha = 1$ for electrons and by $\alpha = [(d^{5/2} + d^3)/(1 + d^{3/2})^2]$ for holes with $d = m_{\text{HH}}/m_{\text{LH}}$, where m_{HH} and m_{LH} are the heavy hole and light hole band masses, respectively [31.12].

Table 31.25 Hall mobilities for electrons (μ_e) and holes (μ_h) obtained at 300 K for relatively pure samples of III–V binaries (in cm^2/Vs)

Fig. 31.10 (a) Electron Hall mobility μ_e in the $\text{Ga}_x\text{In}_{1-x}\text{P}_y\text{As}_{1-y}/\text{InP}$ quaternary and (b) the hole Hall mobility μ_h in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$ ternary, respectively. The experimental data correspond to those for relatively pure samples. The solid lines in (a) and (b) represent the results calculated using (31.26) with $\mu_{\text{al},0} = 3000$ and $50 \text{ cm}^2/\text{Vs}$, respectively

Let us simply express the total carrier mobility μ_{tot} in alloy $\text{A}_x\text{B}_{1-x}\text{C}$ as

$$\frac{1}{\mu_{\text{tot}}(x)} = \frac{1}{x\mu_{\text{tot}}(\text{AC}) + (1-x)\mu_{\text{tot}}(\text{BC})} + \frac{1}{\mu_{\text{al},0}/[x/(1-x)]} \quad (31.26)$$

The first term in (31.26) comes from the linear interpolation scheme and the second term accounts for the effects of alloying.

We plot in Figs. 31.10a and 31.10b the electron Hall mobility in the $\text{Ga}_x\text{In}_{1-x}\text{P}_y\text{As}_{1-y}/\text{InP}$ quaternary (μ_e) and the hole Hall mobility in the $\text{Al}_x\text{Ga}_{1-x}\text{As}$

ternary, respectively. The experimental data correspond to those for relatively pure samples [31.28]. The solid lines in Figs. 31.10a,b represent the results calculated using (31.26) with $\mu_{\text{al},0} = 3000$ and $50 \text{ cm}^2/\text{Vs}$, respectively. The corresponding binary end-point values for μ_{tot} are listed in Table 31.25. For $\text{Ga}_x\text{In}_{1-x}\text{P}_y\text{As}_{1-y}/\text{InP}$, we have considered the quaternary to be an alloy of the constituents $\text{Ga}_{0.53}\text{In}_{0.47}\text{As}$ ($y = 0$) and InP ($y = 1.0$) and we have used the value of μ_{tot} ($\text{Ga}_{0.47}\text{In}_{0.53}\text{As}$) = $13\,000 \text{ cm}^2/\text{Vs}$. It is clear that (31.26) can successfully explain the peculiar composition dependence of the carrier mobility in the semiconductor alloys.

Group III Nitrides

Optical, electrical and mechanical properties of group III nitrides, including of AlN, GaN, InN and their ternary and quaternary compounds are discussed. The driving force for semiconductor nitrides is device applications for emitters and detectors in the visible and ultraviolet (UV) portions of the optical spectrum and high-power amplifiers. Further advances in electronic and optoelectronic devices, which are imperative, require better understanding and precise measurements of the mechanical, thermal, electrical and optical properties of nitride semiconductors. Information available in the literature regarding many of the physical properties of nitrides, especially AlN and InN, is still in the process of evolution, and naturally in the subject of some controversy. This is, in part, a consequence of measurements having been performed on samples of widely varying quality. When possible, these spurious discrepancies have been disregarded. For other materials, too few measurements are available to yield a consensus, in which case the available data are simply reported. The aim of this work is to present the latest

available data obtained by various experimental observations and theoretical calculations.

During the last three decades, developments in the field of group III nitrides have been spectacular, with major breakthroughs taking place in the 1990s. They have been viewed as a highly promising material system for electronic and optoelectronic applications. As members of the group III nitrides family, AlN, GaN, InN and their alloys are all wide-band-gap materials and can crystallize in both wurtzite and zincblende polytypes. The band gaps of the wurtzite polytypes are direct and range from a possible value of ≈ 0.8 eV for InN, to 3.4 eV for GaN, and to 6.1 eV for AlN. GaN alloyed with AlN and InN may span a continuous range of direct-band-gap energies throughout much of the visible spectrum, well into ultraviolet (UV) wavelengths. This makes the nitride system attractive for optoelectronic applications, such as light-emitting diodes (LEDs), laser diodes (LDs), and UV detectors. Commercialization of bright blue and green LEDs and the possibility of yellow LEDs

paved the way for developing full-color displays. If the three primary-color LEDs, including red, produced by the InGaAlAs system are used in place of incandescent light bulbs in some form of a color-mixing scheme, they would provide not only compactness and longer lifetime, but also lower power consumption for the same luminous flux output. Additional possible applications include use in agriculture as light sources for accelerated photosynthesis, and in health care for diagnosis and treatment. Unlike display and lighting applications, digital information storage and reading require coherent light sources because the diffraction-limited optical storage density increases approximately quadratically with decreasing wavelength. The nitride material system, when adapted to semiconductor lasers in blue and UV wavelengths, offers increased data storage density, possibly as high as 50 Gb per disc with 25 Gb promised soon in the Blu-Ray system. Other equally

attractive applications envisioned include printing and surgery.

When used as UV sensors in jet engines, automobiles, and furnaces (boilers), the devices would allow optimal fuel efficiency and control of effluents for a cleaner environment. Moreover, visible-blind and solar-blind nitride-based photodetectors are also an ideal candidate for a number of applications including early missile-plume detection, UV astronomy, space-to-space communication, and biological effects.

Another area gaining a lot of attention for group III–V nitrides is high-temperature/high-power electronic applications, such as radar, missiles, and satellites as well as in low-cost compact amplifiers for wireless base stations, due to their excellent electron transport properties, including good mobility and high saturated drift velocity. The strongest feature of the group III nitrides compared to other wide-band-gap counterparts is the heterostructure technology that it can support. Quantum wells, modulation-doped heterointerfaces, and heterojunction structures can all be made in this system, giving access to new spectral regions for optical devices and new operational regimes for electronic devices. Other attractive properties of the nitrides include high mechanical and thermal stability, and large piezoelectric constants.

One of the main difficulties that have hindered group III nitride research is the lack of a lattice-matched and thermally compatible substrate material. A wide variety of materials have been studied for nitride epitaxy, including insulating metal oxides, metal nitrides, and other semiconductors. In practice, properties other than the lattice constants and thermal compatibility, including the crystal structure, surface finish, composition, reactivity, chemical, and electrical properties, are also important in determining suitability as a substrate. The substrate employed determines the crystal orientation, polarity, polytype, surface morphology, strain, and the defect concentration of the epitaxial films. The most promising results on more conventional substrates so far have been obtained on sapphire, and SiC. Also coming on the scene are thick freestanding GaN templates. Group III–V nitrides have been grown on Si, NaCl, GaP, InP, SiC, W, ZnO, MgAl₂O₄, TiO₂, and MgO. Other substrates have also been used for nitride growth, including Hf, LiAlO₂ and LiGaO₂. Lateral (lattice constant *a*) mismatched substrates lead to substantial densities of misfit and threading dislocations in broad-area epitaxially deposited GaN on foreign substrate, in the range 10^9 – 10^{10} cm^{−2}. An appropriate surface preparation such as nitridation, deposition of a low-temperature

(LT) AlN or GaN buffer layer, selective epitaxy followed by a type of coalescence called lateral epitaxial overgrowth (LEO) or epitaxial lateral overgrowth (ELOG) can reduce dislocation densities down to 10^6 cm^{−2}. However, these numbers are still high compared to extended-defect densities of essentially zero for silicon homoepitaxy, and 10^2 – 10^4 cm^{−2} for gallium arsenide homoepitaxy. Vertical (lattice constant *c*) mismatch creates additional crystalline defects besetting the layers, including inversion domain boundaries and stacking faults. In addition, mismatch of thermal expansion coefficients between the epitaxial films and the substrate induces stress, which can cause crack formation in the film and substrate for thick films during cooling from the deposition temperature. A high density of defects, which increases the laser threshold current, causes reverse leakage currents in junctions, depletes sheet charge-carrier density in heterojunction field-effect transistors, reduces the charge-carrier mobility and thermal conductivity, and is detrimental to device applications and the achievement of their optimal performance. Thus, substrates capable of supporting better-quality epitaxial layers are always needed to realize the full potential of nitride-based devices.

Nearly every major crystal-growth technique has been developed, including molecular beam epitaxy (MBE), hydride vapor-phase epitaxy (HVPE), and metalorganic chemical vapor deposition (MOCVD), in relation to nitride semiconductors. Several modifications to the conventional MBE method have been implemented for group III nitride growth: growth with ammonia or hydrazine (the latter is not attractive due to safety reasons and success of ammonia), plasma-assisted MBE (PAMBE), metalorganic MBE (MOMBE), pulsed laser deposition (PLD), etc. Among other methods, radio-frequency (RF) and electron–cyclotron resonance (ECR) plasma sources are the most commonly employed devices to activate the neutral nitrogen species in the MBE environment. Although all of these epitaxial methods contend with problems related to the lack of native GaN substrates, and difficulty with nitrogen incorporation, remarkable progress in the growth of high-quality epitaxial layers of group III nitrides by a variety of methods has been achieved.

Although many applications based on nitride semiconductors has emerged and some of them are commercially available, as discussed throughout this chapter, there are many contradictions in identification of the basic physical properties of these materials. In this respect, they are not yet mature. Additionally, knowledge of the fundamental properties is crucial not only from the

physics point of view but also when understanding and optimizing the device structures for better performance. In this chapter, therefore, we present the updated fundamental properties of GaN, AlN and InN, including structural, mechanical, thermal, electrical, and optical properties. The aim is to assist readers newly entering this field

and other interested researchers in accessing the most-recent available data. The reader is also urged to peruse the following publications for more detail information in several aspects of ongoing research in group III nitrides. These consist of books [32.1,2], edited books and handbooks [32.3–10], and review papers [32.11–29].

32.1 Crystal Structures of Nitrides

The crystal structures shared by the group III nitrides are wurtzite, zincblende, and rocksalt. At ambient conditions, the thermodynamically stable phase is wurtzite for bulk AlN, GaN, and InN. The cohesive energy per bond in wurtzite variety is 2.88 eV (63.5 kcal/mol), 2.20 eV (48.5 kcal/mol), and 1.93 eV (42.5 kcal/mol) for AlN, GaN, and InN, respectively [32.30]. Although the calculated energy difference ΔE_{W-ZB} between wurtzite and zincblende lattice is small (−18.41 meV/atom for AlN, −9.88 meV/atom for GaN, and −11.44 meV/atom for InN) [32.31] the wurtzite form is energetically preferable for all three nitrides compared to zincblende. The wurtzite structure has a hexagonal unit cell with two lattice parameters a and c in the ratio of $c/a = \sqrt{8/3} = 1.633$ and belongs to the space group of $P6_3mc$. The structure is composed of two interpenetrating hexagonal close-packed (hcp) sublattices, each of which consists of one type of atom displaced with respect to each other along the three-fold c -axis by an amount $u = 3/8 = 0.375$ in fractional coordinates. Each sublattice includes four atoms per unit cell and every atom of one kind (group III atom) is surrounded by four atoms of the other kind (nitrogen), or vice versa, these being coordinated at the edges of a tetrahedron. For actual nitrides, the wurtzite structure deviates from the ideal arrangement by changing the c/a ratio or the u value [32.31]. It should be pointed out that a strong correlation exists between the c/a ratio and the u parameter; when the c/a ratio decreases, the u parameter increases in such a way that those four tetrahedral distances remain nearly constant through a distortion of tetrahedral angles due to long-range polar interactions. These two slightly different bond lengths will be equal if the following relation holds;

$$u = \left(\frac{1}{3}\right) \left(\frac{a^2}{c^2}\right) + \frac{1}{4}. \quad (32.1)$$

Since the c/a ratio also correlates with the difference between the electronegativities of the two constituents, components with the greatest differences show largest departure from the ideal c/a ratio [32.32]. These two

parameters were obtained experimentally by using the four-circle diffractometry technique. For GaN, the c/a ratio and the value of u are measured as 1.627 and 0.377, respectively, which are close to the ideal value [32.33]. AlN deviates significantly from the ideal parameters: $c/a = 1.601$ and $u = 0.382$. Consequently, the interatomic distance and angles differ by 0.01 Å and 3°, respectively. For InN, no reliable data are available due to the lack of single-crystal InN with a suitable size for single-crystal diffractometry measurement.

A phase transition to the rocksalt (NaCl) structure in group III nitrides takes place at very high external pressures. The reason for this is that the reduction of the lattice dimensions causes the inter-ionic Coulomb interaction to favor ionicity over the covalent nature. The structural phase transition was experimentally observed at the following pressure values: 22.9 GPa for AlN [32.34], 52.2 GPa for GaN [32.35], and 12.1 GPa for InN [32.36]. The space-group symmetry of the rocksalt type of structure is $Fm\bar{3}m$, and the structure is six-fold coordinated. However, rocksalt group III nitrides cannot be stabilized by epitaxial growth.

The zincblende structure is metastable and can be stabilized only by heteroepitaxial growth on cubic substrates, such as cubic SiC [32.37], Si [32.38], MgO [32.39], and GaAs [32.40], reflecting topological compatibility to overcome the intrinsic tendency to form the wurtzite phase. In the case of highly mismatched substrates, there is usually a certain amount of zincblende phase of nitrides separated by crystallographic defects from the wurtzite phase. The symmetry of the zincblende structure is given by the space group $F\bar{4}3m$ and composed of two interpenetrating face-centered cubic (fcc) sublattices shifted by one quarter of a body diagonal. There are four atoms per unit cell and every atom of one type (group III nitrides) is tetrahedrally coordinated with four atoms of other type (nitrogen), and vice versa. The overall equivalent bond length is about 1.623 Å for zincblende structures.

Because of the tetrahedral coordination of wurtzite and zincblende structures, the four nearest neighbors and

twelve next-nearest neighbors have the same bond distance in both structures. The main difference between these two structures lies in the stacking sequence of close-packed diatomic planes. The wurtzite structure consists of triangularly arranged alternating biatomic close-packed (0001) planes, for example Ga and N pairs, thus the stacking sequence of the (0001) plane is AaBbAaBb in the (0001) direction. In contrast, the zincblende structure consists of triangularly arranged atoms in the close-packed (111) planes along the (111) direction with a 60° rotation that causes a stacking order of AaBbCcAaBbCc. Small and large letters stand for the the two different kinds of constituents.

Since none of the three structures described above possess inversion symmetry, the crystal exhibits crys-

tallographic polarity; close-packed (111) planes in the zincblende and rocksalt structures and the corresponding (0001) basal planes in the wurtzite structure differ from the ($\bar{1}\bar{1}\bar{1}$) and (000 $\bar{1}$) planes, respectively. In general, group III (Al, Ga, or In)-terminated planes are denoted as (0001) A plane (referred to as Ga polarity) and group V (N)-terminated planes are designated as (000 $\bar{1}$) B plane (referred to as N polarity). Many properties of the material also depend on its polarity, for example growth, etching, defect generation and plasticity, spontaneous polarization, and piezoelectricity. In wurtzite nitrides, besides the primary polar plane (0001) and associated direction (0001), which is the most commonly used surface and direction for growth, many other secondary planes and directions exist in the crystal structure.

32.2 Lattice Parameters of Nitrides

Like other semiconductors [32.41–43], the lattice parameters of nitride-based semiconductors depend on the following factors [32.44]:

1. free-electron concentration, acting via the deformation potential of a conduction-band minimum occupied by these electrons,
2. the concentration of foreign atoms and defects, and the difference between their ionic radii and the substituted matrix ion,
3. external strains (for example, those induced by substrate) and
4. temperature.

The lattice parameters of any crystalline materials are commonly and most accurately measured by high-resolution X-ray diffraction (HRXRD) usually at a standard temperature of 21 °C [32.45] by using the Bond method [32.46] for a set of symmetrical and asymmetrical reflections. In ternary compounds, the technique is also used for determining the composition, however, taking the strain into consideration is of crucial issues pertinent to heteroepitaxy. For nitrides, the composition can be determined with an accuracy of about 0.1% or less, down to a mole fraction of about 1%, by taking into account the elastic parameters of all nitrides and lattice parameters of AlN and InN. Since these factors may distort the lattice constants from their intrinsic values, there is wide dispersion in reported values. Table 32.1 shows a comparison of measured and calculated lattice parameters reported by several groups for AlN, GaN, and InN crystallized in the wurtzite structure.

AlN crystal has a molar mass of 20.495 g/mol when it crystallizes in the hexagonal wurtzite structure. The lattice parameters range from 3.110–3.113 Å for the a parameter and from 4.978–4.982 Å for the c parameter as reported. The c/a ratio thus varies between 1.600 and 1.602. The deviation from that of the ideal wurtzite crystal is probably due to lattice stability and ionicity. Although the cubic form of AlN is hard to obtain, several reports suggested the occurrence of a metastable zincblende polytype AlN with a lattice parameter of $a = 4.38\text{Å}$ [32.47], which is consistent with the theoretically estimated value [32.48]. The lattice parameter of a pressure-induced rocksalt phase of AlN is 4.043–4.045 Å at room temperature [32.49, 50].

GaN crystallized in the hexagonal wurtzite (WZ) structure with four atoms per cell and has a molecular weight of 83.7267 g/mol. At room temperature, the lattice parameters of WZ-GaN platelets prepared under high pressure and high temperatures with an electron concentration of $5 \times 10^{19} \text{ cm}^{-3}$ are $a = (3.1890 \pm 0.0003) \text{ Å}$ and $c = (5.1864 \pm 0.0001) \text{ Å}$ [32.44]. For GaN powder, a and c values are in the range 3.1893–3.190, and 5.1851–5.190 Å, respectively. It has been reported that free charge is the dominant factor responsible for expanding the lattice proportional to the deformation potential of the conduction-band minimum and inversely proportional to carrier density and bulk modulus. Point defects such as gallium antisites, nitrogen vacancies, and extended defects, such as threading dislocations, also increase the lattice constant of group III nitrides to a lower extent in the heteroepitax-

Table 32.1 Measured and calculated lattice constants of AlN, GaN and InN

Compound	Sample	a (Å)	c (Å)	Ref.

	FP-LMTO LDA	3.53	5.54	[32.57]

LDA: Local density approximation; FP-LMTO: pseudopotential linear muffin-tin orbital

ial layers [32.44]. For the zincblende polytype of GaN, the calculated lattice constant based on the measured Ga–N bond distance in WZ-GaN, is $a = 4.503$ Å while the measured values vary between 4.49 and 4.55 Å, indicating that the calculated result lies within acceptable limits [32.37], Si [32.38] MgO [32.39], and GaAs [32.40]. A high-pressure phase transition from the WZ to the rocksalt structure decreases the lattice constant down to $a_0 = 4.22$ Å in the rocksalt phase [32.51]. This is in agreement with the theoretical result of $a_0 = 4.098$ Å obtained from first-principles non-local pseudopotential calculations [32.52].

Due to the difficulties in synthesis and crystal growth, the number of experimental results concerning the physical properties of InN is quite small, and some have only been measured on non-ideal thin films, typically ordered polycrystalline with crystallites in

the 50–500 nm range. Indium nitride normally crystallizes in the wurtzite (hexagonal) structure, like the other compounds of this family, and has a molecular weight of 128.827 g/mol. The measured lattice parameters using a powder technique are in the range of $a = 3.530$ – 3.548 Å and $c = 5.960$ – 5.704 Å with a consistent c/a ratio of about 1.615 ± 0.008 . The ratio approaches the ideal value of 1.633 in samples having a low density of nitrogen vacancies [32.63]. Recently, Paszkowicz [32.64] reported basal and perpendicular lattice parameters of 3.5378 and 5.7033 Å, respectively, for wurtzite-type InN synthesized using a microwave plasma source of nitrogen, having a c/a ratio far from the ideal value. The single reported measurement yields a lattice constant of $a_0 = 4.98$ Å in the zincblende (cubic) form InN occurring in films containing both polytypes [32.63].

32.3 Mechanical Properties of Nitrides

The mechanical properties of materials involve various concepts such as hardness, stiffness constants, Young's and bulk modulus, yield strength, etc. However, the precise determination of the mechanical properties of the group III nitrides is hindered due to the lack of

high-quality large single crystals. However, attempts to estimate and measure the mechanical properties of thin and thick (separated from substrate) epitaxial layers and bulk crystal of nitrides have been made repeatedly. It has been claimed that the most precise technique

used to determine the elastic moduli of compound materials is ultrasonic measurement. Unfortunately, this ultrasonic pulse-echo method requires thick single crystalline samples, about 1 cm thick, to enable measurement of the timing of plane-wave acoustic pulses with sufficient resolution, which makes it almost inapplicable to the group III nitrides. As an optical technique, Brillouin scattering allows the determination of the elastic constants and hence of the bulk moduli through the interaction of light with thermal excitation in a material, in particular acoustic phonons in a crystal. Various forms of X-ray diffraction, such as energy dispersive X-ray diffraction (EDX), angular dispersive X-ray diffraction (ADX) and X-ray absorption spectroscopy (XAS) can also be employed to determine the pressure dependence of the lattice parameters. From these, the experimental equation of state (EOS), (a widely used one is Murnaghan's equation of state) and hence directly the bulk modulus, assuming that it has a linear dependence with the pressure P , can be deduced as [32.65]:

$$V = V_0 \left(1 + \frac{B'P}{B} \right)^{-\frac{1}{B'}}, \quad (32.2)$$

where B and V_0 represent the bulk modulus and unit volume at ambient pressure, respectively, and B' is the derivative of B with respect to pressure. X-ray diffraction leads to the determination of the isothermal bulk modulus, whereas Brillouin scattering leads to the adiabatic bulk modulus. Nevertheless in solids other than molecular solids there is no measurable difference between these two thermodynamic quantities. Besides the experimental investigation many theoretical calculations have been performed on structural and mechanical properties of group III nitrides. Most of the calculations are based on density-functional theory within the local density approximation (LDA) using various types of exchange correlation functionals, and either plane-wave expansion for the pseudopotentials or the linear muffin-tin orbital (LMTO) method.

In hexagonal crystals, there exist five independent elastic constants, C_{11} , C_{33} , C_{12} , C_{13} and C_{44} . C_{11} and C_{33} correspond to longitudinal modes along the [1000] and [0001] directions, respectively. C_{44} and $C_{66} = (C_{11} - C_{12})/2$ can be determined from the speed of sound of transverse modes propagating along the [0001] and [1000] directions, respectively. The remaining constant, C_{13} , is present in combination with four other moduli in the velocity of modes propagating in less-symmetrical directions, such as [0011]. The bulk

modulus is related to the elastic constants by [32.66]

$$B = \frac{(C_{11} + C_{12})C_{33} - 2C_{13}^2}{C_{11} + C_{12} + 2C_{33} - 4C_{13}}. \quad (32.3)$$

In the isotropic approximation, the Young's modulus E and shear modulus G can also be evaluated using the relations $E = 3B(1 - 2\nu)$ and $G = E/2(1 + \nu)$, respectively. The term ν is the Poisson's ratio and is given by $\nu = C_{13}/(C_{11} + C_{12})$ [32.67].

The micro- and nanoindentation methods are widely used in the determination of the hardness of group III nitrides over a wide range of size scales and temperature. Hardness measurements are usually carried out on the (0001) surface of the crystal using a conventional pyramidal or spherical diamond tip, or alternatively, with a sharp triangular indenter (Berhovich). Depth-sensing indentation measurements provide complete information on the hardness and pressure-induced phase transformation of semiconductor materials. Table 32.2 shows the measured and calculated mechanical parameters reported by several groups for AlN, GaN and InN crystallized in wurtzite structure.

From the widely scattered experimental results presented in Table 32.2, the quality of the crystals is clearly one of the main problems for the precise determination of the physical properties of the group III nitrides. This is true especially for InN, where no elastic moduli could be measured, due to difficulties in synthesis and crystal growth. The difference between elastic moduli measured with the same technique (Brillouin scattering) in GaN is further proof that the quality and nature (bulk single crystal or epitaxial layer) of the samples is of primary importance. Nevertheless, with the notable exception of InN, group III nitrides can be considered as hard and incompressible material family members. Their elastic and bulk moduli are of the same order of magnitude as those of diamond. The hardness of semiconductors is often suggested to be dependent on the bonding distance or shear modulus. Indeed, the softest material InN has a smaller shear modulus and larger bonding distance (0.214 nm) compared to GaN (0.196 nm) and AlN (0.192 nm). The temperature dependence of the hardness shows that macroscopic dislocation motion and plastic deformation of GaN and AlN may start at around 1100 °C. The yield strength of bulk single-crystal GaN is found to be 100–300 MPa at 900 °C. The yield strength of AlN was deduced to be \approx 300 MPa at 1000 °C [32.68].

Most applications of group III nitrides depend on the high thermal conductivity of the material, and a funda-

mental understanding of the thermal properties requires precise knowledge of the vibrational modes on the single crystal. Infrared reflection and Raman spectroscopies have been employed to derive zone-center and some zone-boundary phonon modes in nitrides. The A_1 and E_1 branches are both Raman- and infrared-active, the E_2 branches are Raman-active only, and the B_1 branches are inactive. The A_1 and E_1 modes are each split into longitudinal optic (LO) and transverse optic (TO) components, giving a total of six Raman peaks. Table 32.3 gives a list of observed zone-center optical-phonon wave numbers along with those calculated from several techniques employed for AlN, GaN, and InN.

The phonon dispersion spectrum of AlN has a total of twelve branches: three acoustic and nine optical. *Perlin* et al. measured the effect of pressure on the Raman shift of a single-crystal AlN sample synthesized at high pressure and high temperature and showed that the pressure dependence of the three observed peaks could be fitted to a quadratic law up to 14 GPa [32.84]. *McNeil* et al. reported the complete set of Raman-active phonon modes of AlN on single crystals grown by the sublimation recondensation method and noted that Raman peaks and widths are influenced by oxygen-related defects [32.70]. Recently, vibrational properties of epitaxial AlN [deposited on silicon and sapphire substrates at ≈ 325 K by ion-beam-assisted deposition (IBAD)]

have been investigated by *Ribeiro et al.* [32.85]. Raman scattering measurements revealed interesting features and they argued that, due to the extremely weak Raman signal usually exhibited by AlN films, misidentification of some vibration modes can lead to incorrect interpretation of the crystalline quality of AlN films, in which some of the previous mentioned features have been erroneously ascribed [32.86].

The wide spread of studied material has led to some uncertainty in phonon frequencies in GaN, especially of the LO modes. Coupling to plasmons in highly doped material and stress-induced effects due to lattice mismatch with the substrate might play a role in interpretation of the observed phonon frequencies. Moreover, the strong bond in GaN and the light N atoms result in high phonon frequencies that limit the range of observable impurity-related local vibrational modes to even lighter elements at higher frequencies. So far, few reports have appeared for the infrared and Raman modes, which have been associated with local vibrational modes of impurities, dopants, and hydrogen complexes [32.94,95]. The hydrostatic pressure dependence of the zone-center phonon modes has also been determined in n-type bulk

GaN [32.35] and low-residual-doping GaN grown on sapphire [32.96]. The first- and second-order pressure coefficients of the phonon modes have been derived using a polynomial fit.

Raman and infrared spectroscopy studies in InN samples, some grown on (0001) and some on (1102) sapphire substrates, have been undertaken. The infrared (IR) data for A₁(TO) at 448 cm^{-1} and E₁(TO) at 476 cm^{-1} correlate well with the Raman measurements. All six Raman-active modes in the spectra of InN have been observed, with five of them appearing in one InN sample grown on (1102) sapphire. *Kaczmarczyk et al.* [32.97] also studied the first- and second-order Raman-scattering of both hexagonal and cubic InN grown on GaN and GaAs, respectively, covering the acoustic and optical phonon and overtone region. They obtained good agreement with a theoretical model developed by using a modified valence force. The high quality of the samples gives credence to the Raman frequency values as also evidenced by the narrow line widths of all the Raman lines [6.2 cm^{-1} for E₂ (high) and 11.6 cm^{-1} for A₁(LO)]. Details of all the modes are shown in Table 32.3.

32.4 Thermal Properties of Nitrides

32.4.1 Thermal Expansion Coefficients

The lattice parameters of semiconductors are temperature dependent and quantified by thermal expansion coefficients (TEC), which are defined as $\Delta a/a$ or α_a and $\Delta c/c$ or α_c , in and out of plane, respectively. They are dependent on stoichiometry, the presence of extended defects, as well as the free-carrier concentration. As in the case of the lattice parameter, a large scatter in the published data exists for the TEC, particularly for nitrides as they are grown on foreign substrates with different thermal and mechanical properties.

The temperature dependence of the lattice constants a and c , and the thermal expansion coefficients of hexagonal AlN parallel (α_c) and perpendicular (α_a) to the c -axis are shown Fig. 32.1, which can be fitted by the following polynomials within the temperature range $293 < T < 1700$ K;

$$\Delta a/a_0 = -8.679 \times 10^{-2} + 1.929 \times 10^{-4} T + 3.400 \times 10^{-7} T^2 - 7.969 \times 10^{-11} T^3$$

and

$$\Delta c/c_0 = -7.006 \times 10^{-2} + 1.583 \times 10^{-4} T + 2.719 \times 10^{-7} T^2 - 5.834 \times 10^{-11} T^3. \quad (32.4)$$

Using X-ray techniques across a broad temperature range (77–1269 K), it has been noted that the thermal

Fig. 32.1 Variation of the thermal expansion coefficient of AlN on temperature, in and out of the c -plane. After [32.98]

expansion of AlN is isotropic with a room-temperature value of $2.56 \times 10^{-6} \text{ K}^{-1}$ [32.100]. The thermal expansion coefficients of AlN measured by Yim and Paff have mean values of $\Delta a/a = 4.2 \times 10^{-6} \text{ K}^{-1}$ and $\Delta c/c = 5.3 \times 10^{-6} \text{ K}^{-1}$ [32.101]. For AlN powder, the expansion coefficients of $2.9 \times 10^{-6} \text{ K}^{-1}$ and $3.4 \times 10^{-6} \text{ K}^{-1}$ has been reported for the a and c parameters, respectively [32.10].

Thermal expansion of single-crystal wurtzite GaN has been studied in the temperature range 300–900 K [32.102] and 80–820 K [32.103]. Maruska and Tietjen reported that the lattice constant a changes linearly with temperature with a mean coefficient of thermal expansion of $\Delta a/a = \alpha_a = 5.59 \times 10^{-6} \text{ K}^{-1}$. Meanwhile, the expansion of the lattice constant

Fig. 32.2 Lattice parameters c and a of a homoepitaxially grown GaN layer, the corresponding substrate and a Mg-doped bulk crystal as a function of temperature in comparison with literature data. After [32.99]

Fig. 32.3 The temperature dependence of linear expansion coefficients in InN. After [32.103]

c shows a superlinear dependence on temperature parallel to the c -axis with a mean coefficients of thermal expansion of $\Delta c/c = \alpha_c = 3.17 \times 10^{-6} \text{ K}^{-1}$ and $7.75 \times 10^{-6} \text{ K}^{-1}$, over the temperature ranges 300–700 K and 700–900 K, respectively. Sheleg and Savastenko reported a thermal expansion coefficient near 600 K of $(4.52 \pm 0.5) \times 10^{-6} \text{ K}^{-1}$ and $(5.25 \pm 0.05) \times 10^{-6} \text{ K}^{-1}$ for the perpendicular and parallel directions, respectively. Leszczynski and Walker reported α_a values of 3.1×10^{-6} and $6.2 \times 10^{-6} \text{ K}^{-1}$, for the temperature ranges of 300–350 K and 700–750 K, respectively [32.104]. The α_c values in the same temperature ranges, were 2.8×10^{-6} and $6.1 \times 10^{-6} \text{ K}^{-1}$, respectively. Being grown on various substrates with different thermal expansion coefficients leads to different dependencies of the lattice parameter on temperature. The temperature dependence of the GaN lattice parameter has been measured for a bulk crystal (grown at high pressure) with a high free-electron concentration ($5 \times 10^{19} \text{ cm}^{-3}$), a slightly strained homoepitaxial layer with a low free-electron concentration (about 10^{17} cm^{-3}), and a heteroepitaxial layer (also with a small electron concentration) on sapphire. Figure 32.2 shows the lattice parameters of various GaN samples along with the theoretical calculation as a function of temperature for comparison.

The linear thermal expansion coefficients measured at five different temperatures between 190 K and 560 K [32.103] indicate that, along both the parallel and perpendicular directions to the c -axis of InN, these coefficients increase with increasing temperature, as shown in Fig. 32.3. The values range from $3.40 \times 10^{-6} \text{ K}^{-1}$ at 190 K to $5.70 \times 10^{-6} \text{ K}^{-1}$ at 560 K and $2.70 \times 10^{-6} \text{ K}^{-1}$

at 190 K to $3.70 \times 10^{-6} \text{ K}^{-1}$ at 560 K for the perpendicular and parallel directions, respectively.

32.4.2 Thermal Conductivity

GaN and other group III nitride semiconductors are considered for high-power/high-temperature electronic and optoelectronic devices where a key issue is thermal dissipation. Consequently, the thermal conductivity (κ), which is the kinetic property determined by the contributions from the vibrational, rotational, and electronic degrees of freedom, is an extremely important material property. The heat transport is predominantly determined by phonon–phonon Umklapp scattering, and phonon scattering by point and extended defects, such as vacancies (including lattice distortions caused by them), impurities such as oxygen, and isotope fluctuations (mass fluctuation). For pure crystals, phonon–phonon scattering is the limiting process. For most groups III nitrides, due to their imperfection, point defects play a significant role for single crystals, .

The thermal conductivity κ of AlN at room temperature has been theoretically estimated to be 3.19 W/cmK for pure AlN single crystals [32.106]. Values of κ meas-

Fig. 32.4 Thermal conductivity of single-crystal AlN. The solid line alone indicates the theory whereas the others represent measurements of AlN with various concentrations of O. The lower the O concentration, the higher the thermal conductivity. After [32.105]

ured at 300 K are 2.5 [32.107] and 2.85 W/cmK [32.100] for single crystals obtained by the sublimation technique, while measurements made on polycrystalline specimens generally yield lower values (reported maximum value of $\kappa = 2.2$ W/cmK) [32.108], due to enhanced phonon O-related point defects and grain-boundary scattering. A more recent prediction of 5.4 W/cmK for the thermal conductivity of AlN is much larger than the value measured by Witek [32.109]. The measured thermal conductivity as a function of temperature in bulk AlN containing some amount of O is plotted in Fig. 32.4. Also shown is a series of samples with estimated concentrations of O, indicating an overall reduction in the thermal conductivity of AlN with O contamination. In the temperature range of interest, where many of the devices would operate, the thermal conductivity in the sample containing the least amount of O assumes a $T^{-1.25}$ dependence. Recently, even higher thermal conductivity values in the range 3.0–3.3 W/cmK were also reported by [32.110] and [32.111] for freestanding and 300–800 μm -thick AlN samples grown by HVPE originally on Si (111) substrates with a 10^8 cm^{-2} dislocation density.

Fig. 32.5 The thermal conductivity of a 200- μm -thick freestanding GaN sample as a function of temperature. The dashed line indicates a calculation using the boundary scattering limit for a phonon mean free path of 500 μm . Also shown is the $T^{-1.22}$ dependence in the range 80–300 K, and earlier results from [32.112] measured using a 400- μm HVPE sample. After [32.105]

The thermal conductivity of GaN layers grown on sapphire substrates by HVPE were measured by [32.112] as a function of temperature (25–360 K) using a heat-flow method. The room-temperature thermal conductivity was measured as $\kappa \cong 1.3$ W/cmK along the c -axis. This value is slightly smaller than the intrinsic value of 1.7 W/cmK for pure GaN predicted by [32.106] and much smaller than the $\kappa \approx 4.10$ W/cmK calculated by [32.109]. More recently, the room-temperature thermal conductivity of GaN was computed as $\kappa = 2.27$ W/cmK, assuming that there is no isotope scattering [32.105]. This prediction is very close to the measured value of 2.3 W/cmK at room temperature, which increases to over 10 W/cmK at 77 K, in high-quality freestanding GaN samples using a steady-state four-probe method. As can be seen in Fig. 32.5, the measured thermal conductivity of GaN in the temperature range 80–300 K has a $T^{-1.22}$ temperature dependence. This slope is typical of pure adamantane crystals below the Debye temperature, indicating acoustic phonon transport where the phonon–phonon scattering is a combination of acoustic–acoustic and acoustic–optic interactions. This temperature dependence strongly suggests that the thermal conductivity depends mainly on intrinsic phonon–phonon scattering and not on phonon–impurity scattering.

A newer method, scanning thermal microscopy (SThM), has been applied to the measurement of room-temperature thermal conductivity on both fully and partially coalesced lateral epitaxial overgrown (LEO) GaN/sapphire (0001) samples. A correlation between low threading-dislocation density and high thermal conductivity values was established. The reduction in the thermal conductivity with increased dislocation density is expected as threading dislocations degrade the velocity of sound and increase phonon scattering in the material. The highest GaN κ values using this method, in the 2.0–2.1 W/cmK range, were found in the regions of the samples that were laterally grown and thus contained a low density of threading dislocations. This compares with a value of 2.3 W/cmK in a freestanding sample measured by the steady-state four-probe method discussed earlier. An explanation for the dramatic increase from $\kappa \approx 1.3$ W/cmK for the early samples to 2.3 W/cmK for the freestanding sample may be related to the extended-defect concentration (D_d) and the differences in background doping. The effect of dislocation density on the thermal conductivity has been calculated [32.113, 114] by showing that κ remains fairly independent of D_d up to some characteristic value D_d^{char} , after which it decreases by about a factor of two for ev-

ery decade increase in D_d . The thermal conductivity has also been correlated to doping levels in hydride vapor-phase epitaxy (HVPE) n-GaN/sapphire (0001) by STHM on two sets of samples [32.115, 116]. In both sets of data the thermal conductivity decreased linearly with $\log n$, where n is the electron concentration, the variation being about a factor of two decrease in κ for every decade increase in n .

InN single crystals of a size suitable for thermal conductivity measurements have not been obtained. The only measurement of thermal conductivity, which has a room temperature value of $\kappa = 0.45 \text{ W/cmK}$, was made on InN ceramics by using the laser-flash method [32.118]. This value is much lower than the thermal conductivity data obtained from the Leibfried–Schloman scaling parameter [32.117]. A value of about $(0.8 \pm 0.2) \text{ W/cmK}$ is predicted assuming that the thermal conductivity is limited by intrinsic phonon–phonon scattering, but this value may be reduced by oxygen contamination and phonon scattering at defects or increased by very high electronic concentrations.

32.4.3 Specific Heat

The specific heat of a semiconductor has contributions from lattice vibrations, free carriers, and point and extended defects. For good-quality semi-insulating crystal, it is only determined by the lattice vibrations. Due to the lack of defect-free crystals of group III nitrides the specific heat measurements are affected by contributions from free carriers and defects, especially at low temperatures. The specific heat C_p of AlN in the temperature interval 298–1800 K has been approximated [32.119] using the expression

$$C_p = 45.94 + 3.347 \times 10^{-3} T - 14.98 \times 10^{-5} T^2 \text{ J/(molK)}. \quad (32.5)$$

For the higher temperature range 1800–2700 K, an approximation [32.120] using the specific heat of $C_p = 51.5 \text{ J/(molK)}$ at $T = 1800 \text{ K}$, and the estimated value of $C_p = 58.6 \text{ J/(molK)}$ at $T = 2700 \text{ K}$, yielded

$$C_p = 37.34 + 7.86 \times 10^{-3} T \text{ J/(molK)}. \quad (32.6)$$

However, since the free electrons (very effective at low temperatures), impurities, defects (inclusive of point defects), and lattice vibrations contribute to the specific heat, these expressions are very simplistic. The Debye expression for the temperature dependence of the specific heat in a solid at constant pressure (C_p) can be

expressed as

$$C_p = 18R \left(\frac{T}{\theta_D} \right)^3 \cdot \int_0^{\theta_D/T} \frac{x^4 e^x}{(e^x - 1)^2} dx, \quad (32.7)$$

where $x_D \equiv \theta_D/T$, and $R = 8.3144 \text{ J/(mol K)}$ is the molar gas constant. The coefficient in front of the term R has been multiplied by 2 to take into account the two constituents making up the group III nitrides. By fitting the measured temperature-dependent heat capacity to the Debye expression, one can obtain the Debye temperature θ_D related to the heat capacity.

The specific heat obtained from the above approximations coupled with the measured values for constant pressure from the literature are shown in Fig. 32.6 along with the calculated specific heat using the Debye equation for Debye temperature values of 800–1100 K with 50 K increments. The best fit between the data and Debye specific-heat expression for insulators indicates a Debye temperature of 1000 K, which is in good agreement with the value of 950 K reported in [32.117].

Fig. 32.6 Molar specific heat at constant pressure C_p of AlN versus temperature. Open circles represent the experimental data. The solid lines are calculation based on the Debye model for Debye temperatures θ_D in the range 800–1100 K with 50 K increments. The data can be fitted with the Debye expression for $\theta_D = 1000 \text{ K}$, which compares with the value 950 K reported by Slack et al. The data are taken from [32.117]

Fig. 32.7 Molar specific heat at constant pressure C_p , of GaN versus temperature. Open circles represent the experimental data. The solid lines are calculation based on the Debye model for Debye temperatures of θ_D of 500, 600, 700, and 800 K. Unfortunately it is difficult to discern a Debye temperature that is effective over a large temperature range because of the high concentration of defects and impurities in GaN used. The data are taken from [32.122]

To a first approximation the temperature dependence of the specific heat of WZ-GaN at constant pressure (C_p) can be expressed by the following phenomenological expression [32.121]

$$C_p = 9.1 + 2.15 \times 10^{-3} T \text{ cal/(molK)}. \quad (32.8)$$

The specific heat of WZ-GaN has been studied in the temperature range 5–60 K [32.122] and also in the temperature range 55–300 K [32.124], and is discussed in [32.123].

The experimental data from [32.122] and [32.124] are plotted in Fig. 32.7. Also shown in the figure is the calculated specific heat using the Debye expression for Debye temperatures of 500, 600, 700 and 800 K. It is clear that the quality of the data and or sample prevent attainment of a good fit between the experimental data and the Debye curve. Consequently, a Debye temperature with sufficient accuracy cannot be determined. It is easier to extract a Debye temperature using data either near very low temperatures or well below the Debye temperature where the specific heat has a simple cubic

Fig. 32.8 The specific heat of InN with experimental data points, albeit over a small range, and the 600, 700, and 800 K Debye temperature fits. After [32.123]

dependence on temperature [32.125]

$$C_p = 234R \left(\frac{T}{\theta_D} \right)^3. \quad (32.9)$$

Unfortunately, for GaN the samples contain large densities of free carriers and defects, which compromise the application of the Debye specific-heat expression. Consequently, a good fit to the data is not obtained and the Debye temperature extracted in this way is not dependable. Compared to GaN, the Debye temperature obtained in this way for AlN appears more dependable due to a much better fit.

Using the Debye expression for the specific heat and these data, the Debye temperature of InN was obtained as 660 K. The resulting specific-heat curve and the experimental data are plotted in Fig. 32.8. Since the temperature range of these measurements is rather narrow, it is difficult to compare these results and the Debye curve. Good-quality pure InN crystals are extremely difficult to grow and deviations from the Debye curve indicate that the InN samples have significant contributions from non vibrational modes. Using the calculated phonon density of states, the lattice specific heat of InN at constant volume C_v was calculated [32.126] and compared to the experimental values of *Krukowski* et al. [32.123]. This exercise led to the determination of the Debye temperature

θ_D as a function of temperature following the approach of [32.125]. The estimates for θ_D are about

670 K, 580 K, and 370 K at 300 K, 150 K and 0 K, respectively.

32.5 Electrical Properties of Nitrides

GaN and related nitrides being direct and large-band-gap materials lend themselves to a variety of electronic and optoelectronic applications. Advantages associated with a large band gap include higher breakdown voltages, ability to sustain large electric fields, lower noise generation, and high-temperature and high-power operation. Small effective masses in the conduction band minimum lead to reasonably low field mobility, higher satellite-energy separation, and high phonon frequency. Their excellent thermal conductivity, large electrical breakdown fields, and resistance to hostile environments also support the group III nitrides as a material of choice for such applications. The electron transport in semiconductors, including nitrides, can be considered at low and high electric field conditions.

1. At sufficiently low electric fields, the energy gained by the electrons from the applied electric field is small compared to their thermal energy, and therefore the energy distribution of the electrons is unaffected by such a low electric field. Since the scattering rates determining the electron mobility depend on the electron distribution function, electron mobility remains independent of the applied electric field, and Ohm's law is obeyed.
2. When the electric field is increased to a point where the energy gained by electrons from the external field is no longer negligible compared to the thermal energy of the electron, the electron distribution function changes significantly from its equilibrium value. These electrons become hot electrons characterized by an electron temperature larger than the lattice temperature. Furthermore, as the dimensions of the device are shrunk to submicron range, transient transport occurs when there is minimal or no energy loss to the lattice. The transient transport is characterized by the onset of ballistic or velocity-overshoot phenomenon. Since the electron drift velocity is higher than its steady-state value one can design a device operating at higher frequency.

of epitaxial layers. For semiconductor materials, it yields the carrier concentration, its type, and carrier mobility. More specifically, experimental data on Hall measurements over a wide temperature range (4.2–300 K) give information on impurities, imperfections, uniformity, scattering mechanism, etc. The Hall coefficient and resistivity are experimentally determined and then related to the electrical parameters through $R_H = r_H/ne$ and $\mu_H = R_H/\rho$, where n is the free-carrier concentration, e is the unit of electrical charge, μ_H is the Hall mobility, and r_H is the Hall scattering factor. The drift mobility is the average velocity per unit electric field in the limit of zero electric field and is related to the Hall mobility through the Hall scattering factor by $\mu_H = r_H\mu$. The Hall scattering factor depends on the details of the scattering mechanism, which limits the drift velocity. As the carriers travel through a semiconductor, they encounter various scattering mechanisms that govern the carrier mobility in the electronic system. The parameter for characterizing the various scattering mechanisms is the relaxation time τ , which determines the rate of change in electron momentum as it moves about in the semiconductor crystal. Mobility is related to the scattering time by

$$\mu = \frac{q\langle\tau\rangle}{m^*}, \quad (32.10)$$

where μ^* is the electron effective mass, q is the electronic charge, and $\langle\tau\rangle$ is the relaxation time averaged over the energy distribution of electrons. The total relaxation time, τ_T when various scattering mechanisms are operative is given by Matthiessen's rule

$$\frac{1}{\tau} = \sum_i \frac{1}{\tau_i}, \quad (32.11)$$

where i represents each scattering process. The major scattering mechanisms that generally governs the electron transport in group III–V semiconductors is also valid for group III nitrides. They are briefly listed as follows:

1. Ionized-impurity scattering is due to the deflection of free carriers by the long-range Coulomb potential of the charged centers caused by defects or intentionally doped impurities. This can be considered as

32.5.1 Low-Field Transport

The Hall effect is the most widely used technique to measure the transport properties and assess the quality

a local perturbation of the band edge, which affects the electron motion.

2. Polar longitudinal-optical (LO) phonon scattering is caused by the interaction of a moving charge with the electric field induced by electric polarization associated with lattice vibration due to the ionic nature of the bonds in polar semiconductors such as nitrides.
3. Acoustic phonon scattering through the deformation potential arises from the energy change of the band edges induced by strain associated with acoustic phonons, where the scattering rate increases with the wave vectors of the phonons.
4. Piezoelectric scattering arises from the electric fields that are produced by the strain associated with phonons in a crystal without inversion symmetry, particularly in wide-band-gap nitrides.
5. Because of the high density of dislocations and native defects induced by nitrogen vacancies in GaN, dislocation scattering and scattering through nitrogen vacancies has also been considered as a possible scattering mechanism. Dislocation scattering is due to the fact that acceptor centers are introduced along the dislocation line, which capture electrons from the conduction band in an n-type semiconductor. The dislocation lines become negatively charged and a space-charge region is formed around it, which scatters electrons traveling across the dislocations, thus reducing the mobility.

Gallium Nitride

Electron mobility in GaN is one of the most important parameters associated with the material, with a great impact on devices. It has been the subject of intensive studies in recent years from both the experimental and theoretical points of view. Experimental investigation of the temperature-dependent carrier mobility and concentration can be used to determine the fundamental material parameters and understand the carrier scattering mechanism along with an accurate comparison with theory [32.127, 128]. Compared to other group III–V semiconductors, such as GaAs, GaN possesses many unique material and physical properties, as discussed in the previous section. However, the lack of high-quality material, until very recently, prevented detailed investigations of carrier transport. The earlier transport investigations had to cope with poor crystal quality and low carrier mobility, well below predictions [32.129, 130]. Early MBE layers exhibited mobilities as high as $580 \text{ cm}^2/\text{Vs}$ on SiC substrates, which at that time were not as commonly used as in recent times [32.131]. Typically, however, MBE-

grown films produce much lower mobility values of $100\text{--}300 \text{ cm}^2/\text{Vs}$ [32.132]. Different models were used to explain the observed low electron mobilities in GaN, especially at low temperatures. Scattering of electrons at charged dislocation lines [32.132–136] and scattering through elevated levels of point defects [32.137, 138], such as nitrogen vacancies [32.139, 140] were considered as a possible mechanisms responsible for these observations. These scattering mechanisms were investigated by studying the temperature dependence of the carrier concentration and electron mobility. It has been argued that mobility is related to the dislocation density (N_{dis}) and free-carrier concentration (n) via a $\mu_{\text{dis}} \propto \sqrt{n}/N_{\text{dis}}$ relationship [32.135]. At low carrier concentrations ($< 5 \times 10^{17} \text{ cm}^{-3}$), the mobility decreases due to charged dislocation scattering, while at higher carrier concentrations ionized impurities are the dominant mechanism determining the mobility. The temperature dependence of the mobility for samples where dislocations play a dominant role shows that the mobility increases monotonically with temperature, following a $T^{2/3}$ dependence. Electron mobility limited by nitrogen-vacancy scattering was taken into account in n-type GaN grown by MOVPE by Zhu and Sawaki [32.139] and Chen et al. [32.140]. A good fit was obtained between the calculated and experimental results. The estimated mobility shows a $T^{-2/2}$ temperature dependence and it was argued that the measured mobility is dominated by ionized-impurity and dislocation scattering at low temperatures, but polar optical phonon and nitrogen-vacancy scattering at high temperatures.

Hall mobility and electron concentration in undoped GaN were investigated as a function of the thickness of buffer layers and epilayers. Nakamura [32.141] made Hall-effect measurements on undoped GaN layers grown by MOVPE on GaN buffer/sapphire substrates. As the thickness of the buffer layer increased from 100 \AA , the mobility also increased up to a thickness of 200 \AA . At larger thicknesses the mobility began to decrease. The value of the mobility was $600 \text{ cm}^2/\text{Vs}$ at room temperature for a 200 \AA thick layer. The electron concentration was a minimum at 520 nm and increased monotonically as the buffer thickness increased. The mechanism responsible for this observation was not clearly established. Götz et al. [32.142] have studied the effect of the layer thickness on the Hall mobility and electron concentration in unintentionally doped n-type GaN films grown by HVPE on sapphire substrates, which is pretreated with either ZnO or GaCl. They found that the mobility increased and the carrier concentration decreased as the thickness of the epilay-

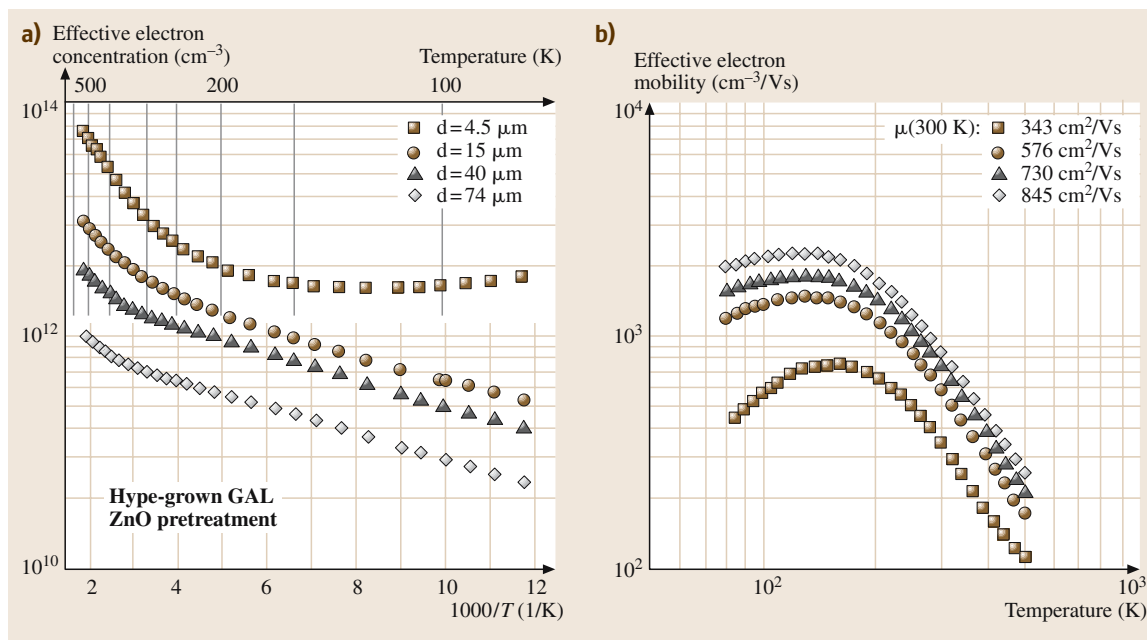

Fig. 32.9a,b Effective electron concentration versus reciprocal temperature (a) and effective electron mobility versus temperature (b), as determined from Hall-effect measurements under the assumption of uniform film properties. After [32.142]

ers increased, as shown in Fig. 32.9. They related this variation to a nonuniform distribution of electrically active defects through the film thickness for both types of films. For GaCl-pretreated sapphire the presence of a highly conductive, 200-nm-thick near-interface layer was assumed to account for the observed phenomena. For ZnO-pretreated sapphire, the Hall-effect data indicated a continuous reduction of the defect density with increasing film thickness.

Since GaN layers are often grown on foreign substrates with very different properties, a degenerate layer forms at the interface caused by extended defects and impurities. Experiments show that, even for thick GaN grown by HVPE, the degenerate interfacial layer makes an important contribution to the Hall conductivity. Look and Molnar [32.143] investigated the Hall effect in the temperature range 10–400 K in HVPE-grown layers on sapphire substrate by assuming a thin, degenerate n-type region at the GaN/sapphire interface. This degenerate interfacial region dominates the electrical properties below 30 K, but also significantly affects those properties even at 400 K, and can cause a second, deeper donor to falsely appear in the analysis. The curve of mobility versus temperature is also affected in that the whole curve is shifted downward from the true, bulk curve. A model

consisting of two layers was constructed to interpret these observations and the result is shown in Fig. 32.10.

Hall mobilities for electron concentrations in the range $\approx 10^{16}$ – 10^{19} cm^{-3} for undoped and intentionally doped (the commonly used donors Si and Ge, which substitute for Ga, are shallow donors with almost identical activation energies for ionization) GaN layers grown by different growth techniques, Fig. 32.11. The most clearly observed trend is that the mobility shows no signs of leveling down to the lowest carrier concentration reported, and the mobility values are practically the same, irrespective of the growth techniques and dopants used, which reflects transport properties inherent to GaN, not to the extrinsic effects. The room-temperature mobility measured by Nakamura et al. [32.144] is $600 \text{ cm}^2/\text{Vs}$ for an electron concentration of $\approx 3 \times 10^{16} \text{ cm}^{-3}$, and decreases slowly with increasing carrier concentration, reaching a value of about $100 \text{ cm}^2/\text{Vs}$ at a carrier concentration of $3 \times 10^{18} \text{ cm}^{-3}$. For an electron concentration of $1 \times 10^{18} \text{ cm}^{-3}$, the mobility is $250 \text{ cm}^2/\text{Vs}$. A higher room-temperature mobility of $845 \text{ cm}^2/\text{Vs}$ at an electron concentration of $\approx 6 \times 10^{16} \text{ cm}^{-3}$ was achieved by Götz et al. [32.142]. In later publications, due to the advent of high-quality samples grown by several

(b) Uncorrected Hall-mobility data (squares) and fit (solid line), and corrected data (triangles) and fit (dashed line) versus temperature. After [32.134]

growth techniques, there is a significant improvement in reported room-temperature mobility values. Nakamura et al. [32.145] and Binari and Dietrich [32.146] were able to obtain 900 cm²/Vs room-temperature mobility at an electron concentration of 3×10^{16} cm⁻³ and 5×10^{16} cm⁻³, respectively. Recently, even higher electron mobilities of 1100 cm²/Vs at room temperature and 1425 cm²/Vs at 273 K were reported in [32.93,147] for a 200- μ m-thick freestanding n-type GaN template grown by HVPE. This achievement was attributed to the excellent crystalline structure of the GaN sample with low levels of compensation and the defect-related scattering. A quantitative comparison with theoretical calculations demonstrates that the one-layer and one-donor conductance model is sufficient to account for the measured data in the entire temperature range without considering any dislocation scattering and any adjustable parameter other than the acceptor concentration. The measured temperature-dependent Hall mobility, carrier concentration and Hall scattering factor is shown in Fig. 32.12 along with the best-fit theoretical calculation based on an iterative solution of the Boltzmann equation. As shown, quantitative agreement with the measured mobility in the entire temperature range was obtained to within about 30%. Heying et al. [32.148] investigated both the morphology and electrical properties of homoepitaxial GaN layers grown by MBE as a function of Ga/N ratio. GaN films grown with higher Ga/N ratios (intermediate regime) showed fewer pits with areas of atomically flat surface, which gives the highest mobility ≈ 1191 cm²/Vs reported so far at room tem-

Fig. 32.11 The 300 K Hall mobility versus free electron concentration for GaN from various groups using both MOVPE and MVE. The open circles are from unintentionally doped samples and the solid circles are from samples doped with either Si or Ge. After [32.150]

perature. Koleske et al. [32.149] investigated the effect of the AlN nucleation layer on the transport properties of GaN films grown on 6H- and 4H-SiC substrate. Room-temperature electron mobilities of 876, 884, and 932 cm²/Vs were obtained on 6H-SiC, 4H-SiC, and 3.5° off-axis 6H-SiC substrates. They attributed the observed high electron mobilities to the improved AlN morphology and reduction in screw-dislocation density near the AlN/GaN interface.

The *solid line* is the calculated result using $N_a = 2.4 \times 10^{15} \text{ cm}^{-3}$, representing the best fit to the measured results. The *upper* and *lower dotted lines* are the calculated results using $N_a = 1.4 \times 10^{15}$ and $3.4 \times 10^{15} \text{ cm}^{-3}$. (b) The measured Hall densities n_H (*solid squares*) as a function of reciprocal temperature from the GaN template grown by HVPE. The *open circles* represent the carrier density corrected by the Hall factor, $n = n_H r_H$. The *solid line* is the fit to the theoretical expression of charge balance with hole and neutral acceptor densities neglected. (c) Temperature dependence of the calculated Hall factor, r_H . After [32.93]

The thermal activation energy of free carriers has also been extracted from the temperature-dependent Hall concentration and mobility measurements by fitting the simple exponential dependence of the carrier temperature on inverse temperature, by the two-band model and by other theoretical fitting techniques. It could be concluded that the activation energy of n-type GaN free carriers lies in the range 14–36 meV, depending on the extent of screening [32.93, 144, 151, 152]. In the dilute limit, the values are close to 30 meV.

In order to analyze the mobility data, one must understand the scattering processes that dominate mobility at different temperatures. Monte Carlo simulation of the electron velocity in GaN as a function of electric field at different doping concentration and temperature predicted a peak drift velocity of $2 \times 10^7 \text{ cm/s}$ at an electric field of $\approx 1.4 \times 10^5 \text{ V/cm}$ for an electron concentration of 10^{17} cm^{-3} [32.153, 154]. These values show that an electron mobility as high as $900 \text{ cm}^2/\text{Vs}$ could be achieved in the case of uncompensated GaN at room temperature with $\approx 10^{17} \text{ cm}^{-3}$ doping concentration. As discussed above, in the case of high-quality samples with very low compensation, a mobility of even more than $900 \text{ cm}^2/\text{Vs}$ at room temperature with a similar doping concentration has been reported. Albrecht et al. [32.155] calculated the electron mobility for different concentrations of ionized impurities and at different temperatures by using a Monte Carlo simulation technique based on

empirical pseudopotential band-structure calculations. For practical use they have also derived an analytical expression describing the dependence of the mobility on temperature and ionized-impurity concentration as

$$\frac{1}{\mu_e} = a \left(\frac{N_I}{10^{17} \text{ cm}^{-3}} \right) \ln \left(1 + \beta_{CW}^2 \right) \left(\frac{T}{300 \text{ K}} \right)^{-1.5} + b \left(\frac{T}{300 \text{ K}} \right)^{1.5} + c \frac{1}{\exp(\Theta/T) - 1}, \quad (32.12)$$

where

$$\Theta = \frac{\hbar \omega_{LO}}{k_B} = 1065 \text{ K},$$

$$\beta_{WC}^2 = 3.00 \left(\frac{T}{300 \text{ K}} \right)^2 \left(\frac{N_I}{10^{17} \text{ cm}^{-3}} \right),$$

$$N_I = (1 + k_c)/N_D$$

and

$$a = 2.61 \times 10^{-4} \text{ Vs/cm}^2,$$

$$b = 2.90 \times 10^{-4} \text{ Vs/cm}^2 \quad \text{and}$$

$$c = 1.70 \times 10^{-2} \text{ Vs/cm}^2.$$

Here N_D is the ionized donor concentration in cm^{-3} and $k_c = N_A/N_D$ is the compensation ratio. By the mobility calculated using this analytical expression and that calculated by Monte Carlo simulation, a reasonable agreement with a maximum error of 6% is realized

After [32.156]

between the temperature range 300–600 K, and ionized donor concentration of 10^{16} – 10^{18} .

The calculation of the low-field electron mobility in GaN has also been carried out by using different calculation techniques. *Chin et al.* [32.129] have used the variational principle to calculate low-field electron mobilities as a function of temperature for carrier concentrations of 10^{16} , 10^{17} , and 10^{18} cm^{-3} with the compensation ratio as a parameter. GaN exhibits maximum mobilities in the range 100–200 K, depending on the electron density and compensation ratio, with lower electron densities peaking at lower temperature. This behavior is related to the interplay of piezoelectric acoustic-phonon scattering at low carrier concentration and ionized-impurity scattering at higher carrier concentrations. The maximum polar-mode optical-phonon scattering-limited room-temperature mobility in GaN is found to be about $1000 \text{ cm}^2/\text{Vs}$. Although a degree of correlation is achieved with the experimental data, there is a disparity, which is attributed to the structural imperfection and overestimated compensation ratio. Typical compensation ratios observed for MOCVD- and MBE-grown films are about 0.3, although

a lower ratio of ≈ 0.24 was reported for HVPE-grown crystals. Compensation reduces the electron mobility in GaN for a given electron concentration. *Rode and Gaskill* [32.130] have used an iterative technique, which takes into account all major scattering mechanisms, for low-field electron mobility in GaN for the dependence of the mobility on the electron concentration, but not on temperature. The result was applied to the Hall-mobility data published by *Kim et al.* [32.157] and a good fit between theory and experiment is demonstrated within 2.5% for the lowest-doped samples with free-electron concentrations of 7.24×10^{17} and $1.74 \times 10^{17} \text{ cm}^{-3}$. However, there is a significant disagreement for the more-heavily-doped samples having much higher free-electron concentrations. The Born approximation applied to the ionized-impurity scattering might be the reason for poor fitting at high electron concentrations. By assuming uncompensated material and carrier freeze out onto donors, the ionization energy was theoretically determined to be about 45 and 57 meV for the best-fitted samples with free-electron concentrations of 7.24×10^{17} and $1.74 \times 10^{17} \text{ cm}^{-3}$, respectively. Recent developments in

the major growth techniques like HVPE, MOCVD, and MBE for GaN and other group III nitride semiconductors have led to the growth of high-quality epitaxial layers [32.158–160], which allowed the comparison of the Hall data with theory to commence. Dhar and Gosh [32.156] have calculated the temperature and doping dependencies of the electron mobility using an iterative technique, in which the scattering mechanisms have been treated beyond the Born approximation. The compensation ratio was used as a parameter with a realistic charge-neutrality condition. They tested their model with the experimental Hall data taken from the literature [32.94, 143–145, 161–168]. Reasonable agreement was achieved between these data points and the

Fig. 32.14 (a) Low-field electron mobility as a function of doping concentration in GaN at room temperature. The curve represents the best approximate equation. (b) Temperature dependencies of low-field electron mobility in wurtzite GaN at different values of doping concentration. Curves represent the best approximate equations. 1: $N = 3 \times 10^{16} \text{ cm}^{-3}$, 2: $N = 10^{17} \text{ cm}^{-3}$, 3: $N = 1.5 \times 10^{17} \text{ cm}^{-3}$, 4: $N = 2 \times 10^{17} \text{ cm}^{-3}$, 5: $N = 3.5 \times 10^{17} \text{ cm}^{-3}$, 6: $N = 10^{18} \text{ cm}^{-3}$, 7: $N = 3 \times 10^{18} \text{ cm}^{-3}$. After [32.169]

calculation over a wide range of temperatures and electron concentrations, as shown in Fig. 32.13. They also investigated the effect of the degenerate layer at the GaN/substrate interface to extract reliable experimental values of the bulk electron mobility and concentration.

Besides the numerical simulation techniques mentioned above, recently Mnatsakanov et al. [32.169] derived a simple analytical approximation to describe the temperature and carrier concentration dependencies of the low-field mobility in wide temperature ($50 \leq T \leq 1000 \text{ K}$) and carrier concentration ($10^{14} \leq N \leq 10^{19} \text{ cm}^{-3}$) ranges. At the first step of this model, an adequate approximation of the doping-level dependence of the mobility at room temperature is used on the base of the Goughy–Thomas approximation [32.170]

$$\mu_i(N) = \mu_{\min,i} + \frac{\mu_{\max,i} - \mu_{\min,i}}{1 + \left(\frac{N}{N_{g,i}}\right)^{\gamma_i}}, \quad (32.13)$$

where $i = n, p$ for electrons and holes, respectively, $\mu_{\min,i}$, $\mu_{\max,i}$, $N_{g,i}$ and γ_i are the model parameters dependent on the type of semiconductor materials, and N is the doping concentration. Figure 32.14a shows the comparison between the calculated low-field electron mobility as a function of doping level and some experimental data on the room-temperature electron mobility in GaN. The proposed approximation provides rather good agreement with the experimental data. For the temperature-dependent mobility calculation, the authors derived the following equation by taking into account the main scattering mechanisms:

$$\mu_i(N, T) = \mu_{\max,i}(T_0) \frac{B_i(N) \left(\frac{T}{T_0}\right)^{\beta_i}}{1 + B_i(N) \left(\frac{T}{T_0}\right)^{\alpha_i + \beta_i}}, \quad (32.14)$$

where

$$B_i(N) = \left(\frac{\mu_{\min,i} + \mu_{\max,i} \left(\frac{N_{g,i}}{N} \right)^{\gamma_i}}{\mu_{\max,i} - \mu_{\min,i}} \right) \Big|_{T=T_0}.$$

Figure 32.14b presents the calculated temperature-dependent electron mobility and experimental data reported in the literature and a good agreement is realized. Ionized-impurity scattering is the dominant mechanism at low temperatures, the mobility increases with increasing temperature, at high temperatures mobility is limited by polar optical-phonon scattering, and the mobility decrease with increasing temperature. Finally, many material and physical parameters of GaN were not available for some of the previous simulations where those parameters were treated as adjustable parameters. Needless to say, reliable parameters are required in the calculation of the electron mobility and in the interpretation of experimental results to gain more accuracy.

Aluminium Nitride

Due to the low intrinsic carrier concentration, and the deep native-defect and impurity energy levels (owing to the wide band gap of AlN ≈ 6.2 eV at 300 K), the electrical transport properties of AlN have not been studied extensively and have usually been limited to resistivity measurements. Resistivities in the range $\rho = 10^7 - 10^{13} \Omega\text{cm}$ have been reported for unintentionally doped AlN single crystals [32.171, 172], a value consistent with other reports [32.173–175]. The conductivity exhibited an Arrhenius behavior for all crystals and the activation energies were reported to be 1.4 eV for temperatures of 330 and 400 K and 0.5 eV between 300 and 330 K. Intentional doping of AlN has resulted in both n- and p-type AlN by introducing Hg and Se, respectively. Gorbato and Kamyshev [32.176] obtained the n-type conductivity of polycrystalline AlN with the incorporation Si. Unintentionally doped n-AlN films grown by a modified physical-transport technique by Rutz [32.177] had a resistivity as low as 400 Ωcm . Although the source of the electrons has not been determined, Rutz et al. [32.178] observed an interesting transition in their AlN films in which the resistivity abruptly decreased by two orders of magnitude with an increase in the applied bias. This observation found applications in switchable resistive memory elements that are operated at 20 MHz. It has been concluded by Fara et al. [32.179], who reported the theoretical evidence, based on ab initio density-functional calculations, for acceptors, donors, and native defects in AlN,

Fig. 32.15 The phonon-limited electron drift mobility in AlN plotted as a function of temperature for $m^* = 0.48$. The upper and lower solid curves are the phonon-limited electron drift mobility calculated using $m^* = 0.42$ and 0.52, respectively. After [32.129]

for the semi-insulating character of AlN that acceptors are deeper (Be ≈ 0.25 , Mg ≈ 0.45) and less soluble in AlN than in GaN, and both the extrinsic donors Si_{Al} and C_{Al}, and the native donor V_N are found to be deep (about 1–3 eV below the conduction). Consequently, doped AlN may in general turn out to be semi-insulating, when attained using Al-rich conditions, in agreement with the known doping difficulties of high-Al-content AlGaN alloys.

As far as the mobility of AlN is concerned, in early studies, Edwards et al. [32.171] and Kawabe et al. [32.172] carried out some Hall measurements in p-type AlN, which produced a very rough estimate of the hole mobility of $\mu_p = 14 \text{ cm}^2/\text{Vs}$ at 290 K. Later work on carbon-doped material has resulted in highly conductive p-type AlN with hole mobilities on the order of 60 cm^2/Vs for carbon doping of 10^{18} cm^{-3} [32.180]. Theoretical calculations to estimate the mobility in AlN have only been made by Chin et al. [32.129]. Since AlN is an insulator with extremely low carrier concentration, only phonon-limited scattering processes were considered in the calculation of the temperature-dependent mobility, as shown in Fig. 32.15. The mobility was found to decline rapidly at high temperatures, with a value of about 2000 cm^2/Vs at 77 K, dropping to 300 cm^2/Vs at 300 K for optical-phonon-limited mobility.

Indium Nitride

InN suffers from the lack of a suitable substrate material, causing a high concentration of extended defects in the films. Sapphire substrate is usually used for InN growth, but the difference in lattice constants between InN and sapphire is as large as 25% and even more than 19% with the other nitrides. A large disparity of the atomic radii of In and N is an additional contributing factor to the difficulty of obtaining InN of good quality. Because of all these factors, the electron mobilities obtained from various films have varied very widely. Electrical properties vary also substantially with the choice of growth techniques. A range of film-deposition techniques, such as reactive-ion sputtering, reactive radio-frequency (RF) magnetron sputtering, metalorganic vapor-phase epitaxy (MOVPE) and MBE, has been used. Table 32.4 gives updated values of electron mobility and concentration in InN films grown by various growth techniques.

The transport properties reported in the literature are mostly based on Hall-effect measurements, assuming the Hall scattering factor to be unity. In majority, electron mobilities often remain relatively poor, despite predicted values as high as 3000 cm²/Vs at room temperature for InN [32.198]. It is widely believed that nitrogen

vacancies lead to large background electron concentrations, which is responsible for the observed low electron mobility. An empirical linear relationship between the electron mobility and electron concentration can be deduced from the table for a series of InN films, although not all films exhibit this type of behavior. A systematic study carried out by Tansley et al. [32.199] indicates that the electron concentration decreases as the nitrogen density is increased in the growth plasma in reactive-ion sputtering. Although the reported time is relatively old, the maximum mobility of 2700 cm²/Vs at an electron concentration of 5 × 10¹⁶ cm⁻³ was reported for RF reactive-ion sputtered growth of InN. Early study of the electron mobility of InN as a function of the growth temperature indicates that the mobility of InN grown by ultrahigh-vacuum electron-cyclotron resonance-radio-frequency magnetron sputtering (UHVECR-RMS) can be as much as four times the mobility of conventionally grown (vacuum-deposited) InN [32.187]. However, more recent work indicates a progressive improvement in electrical properties of InN films grown by vacuum-deposition techniques, including MBE and MOVPE. Values of the electron mobility as high as 1420 cm²/Vs at an electron concentration of 1.4 × 10¹⁸ cm⁻³ were re-

Fig. 32.16a,b The electron drift and Hall mobilities of InN as a function of temperature for (a) $n = 5 \times 10^{16} \text{ cm}^{-3}$ for compensation ratios of 0.00 and 0.60; and (b) $8 \times 10^{16} \text{ cm}^{-3}$ for compensation ratios of 0.00, 0.30, 0.60, and 0.75; all experimental data are from [32.129]

ported for InN layers grown by plasma-assisted MBE using a low-temperature-grown GaN intermediate layer and a low-temperature-grown InN buffer layer. Hall measurements in InN films grown on AlN buffer layers, which are in turn grown on sapphire, indicated an electron mobility of $2100 \text{ cm}^2/\text{Vs}$ with a relatively low electron concentration ($4 \times 10^{17} \text{ cm}^{-3}$) at room temperature in material grown by MBE. Very high inadvertent-donor concentrations ($> 10^{18} \text{ cm}^{-3}$) seem to be one of the major problems for further progress of device applications of InN. O_N and Si_In and possible interstitial H have been proposed to be the likely dominant defects responsible for high electron concentration for state-of-the-art MBE-grown InN, based on their low formation energies [32.200, 201].

The electron mobility in InN has been calculated using the variational principle for a range of temperatures, carrier concentrations, and compensation ratios [32.129]. Figure 32.16 shows the theoretical results with experimental mobility values taken

from Tansley and Foley [32.182]. The calculated peak mobilities are found to be 25 000, 12 000, and $8000 \text{ cm}^2/\text{Vs}$ for 10^{16} , 10^{17} , and 10^{18} cm^{-3} , respectively, at different temperatures (100–200 K), depending on the electron density and the compensation ratio. This is due to the interplay of piezoelectric acoustic-phonon scattering at low concentrations and ionized-impurity scattering at high temperatures. These two mechanisms are the dominant scattering mechanisms below 200 K, while polar-mode optical-phonon scattering is the most significant process above this temperature. The low-concentration limit for room-temperature mobility in uncompensated InN is estimated to be $4400 \text{ cm}^2/\text{Vs}$.

32.5.2 High-Field Transport

Ensemble Monte Carlo simulations have been the popular tools for the theoretical investigation of steady-state electron transport in nitrides. In particular, the steady-state velocity–field characteristics have been determined for AlN [32.203, 204], GaN [32.154, 155, 205–208], and InN [32.209, 210]. These reports show that the

Fig. 32.17 The velocity–field characteristics associated with wurtzite GaN, InN, AlN, and zincblende GaAs. In all cases, we set the temperature to 300 K and the doping concentration to 10^{17} cm^{-3} . The critical fields at which the peak drift velocity is achieved for each velocity–field characteristic are clearly marked: 140 kV/cm for GaN, 65 kV/cm for InN, 450 kV/cm for AlN, and 4 kV/cm for GaAs. After [32.202]

drift velocity initially increases with the applied electric field, reaches a maximum and then decreases with further increases in the field strength. Inter-valley electron transfer plays a dominant role at high electric fields, leading to a strongly inverted electron distribution and to a large negative differential resistance (NDR). The reduction in the drift velocities was attributed to the transfer of electrons from the high-mobility Γ -valley to the low-mobility satellite X-valley. The onset electric field and peak drift velocities, however, show some disparity among the reported calculations due to the variety of degree of approximation and material physical constants used. A typical velocity–field characteristic for bulk group III nitrides at room temperature is shown in Fig. 32.17, along with the well-studied GaAs data

used to test the author's Monte Carlo model. With the doping concentration set to 10^{17} cm^{-3} , InN has the highest steady-state peak drift velocity: $4.2 \times 10^7 \text{ cm/s}$ at an electric field of 65 kV/cm . In the case of GaN and AlN, steady-state peak drift velocities are rather low and occur at larger electric fields: $2.9 \times 10^7 \text{ cm/s}$ at 140 kV/cm for GaN, and $1.7 \times 10^7 \text{ cm/s}$ at 450 kV/cm for AlN.

Another interesting aspect of electron transport is its transient behavior, which is relevant to short-channel devices with dimensions smaller than $0.2 \mu\text{m}$, where a significant overshoot is expected to occur in the electron velocity over the steady-state drift velocity.

Transient electron transport and velocity overshoot in both wurtzite and zincblende GaN, InN, and AlN were studied theoretically by a number of groups. Foutz

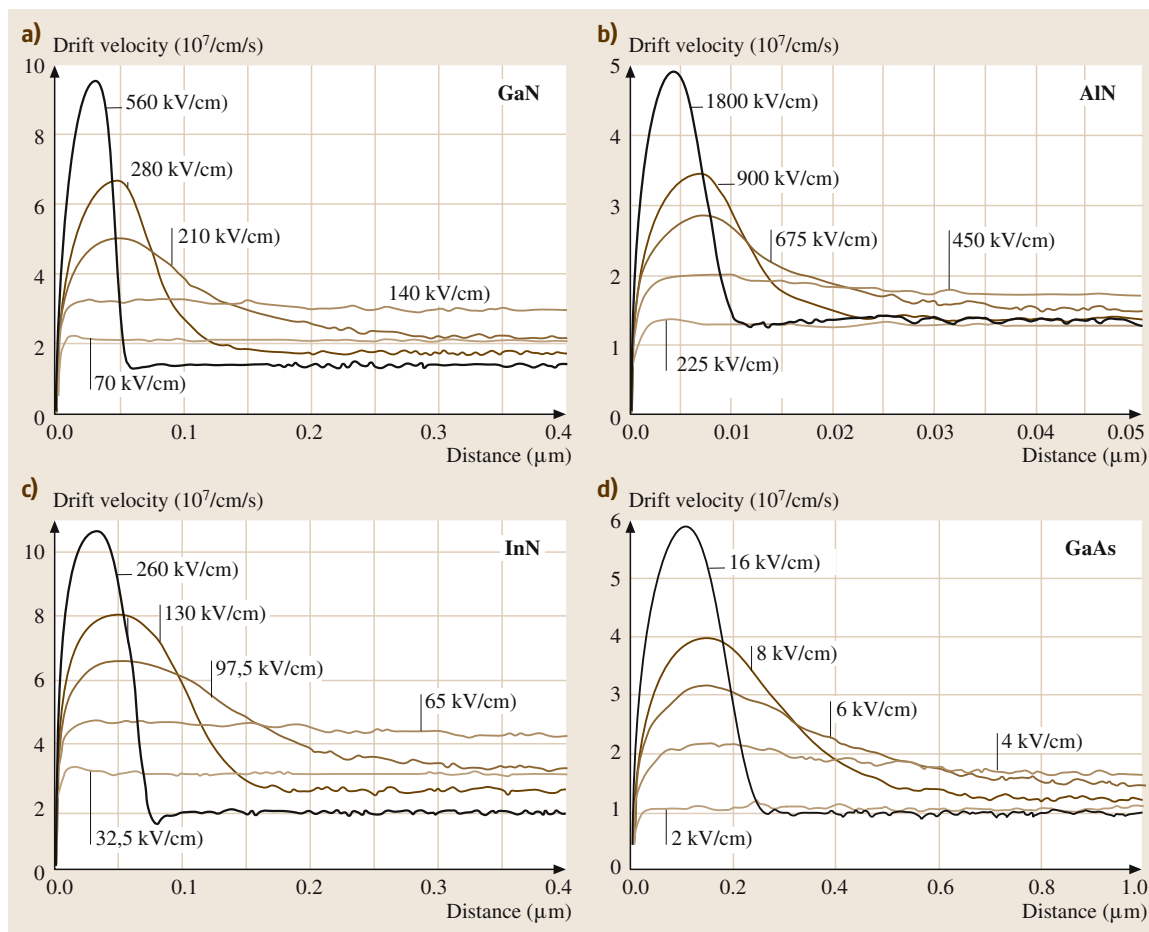

Fig. 32.18a–d The average electron velocity as a function of the displacement for various applied fields for the cases of (a) GaN, (b) InN, (c) AlN, and (d) GaAs. In all cases, we have assumed an initial zero-field electron distribution, a crystal temperature of 300 K, and a doping concentration of 10^{17} cm^{-3} . After [32.202]

et al. [32.202] employed both Monte Carlo simulations and one-dimensional energy-momentum balance techniques. They used a three-valley model for the conduction band by taking the main scattering mechanisms, such as ionized impurity, polar optical-phonon, acoustic-phonon through deformation potential and piezoelectric, and inter-valley scatterings into account. In particular, they examined how electrons, initially in equilibrium, respond to the instant application of a constant electric field. Figure 32.18 shows the average velocity of the electrons in AlN, GaN, and InN as a function of distance. According to their calculation, electron velocity overshoot only occurs when the electric field exceeds a certain critical value unique to each material and it lasts over a certain distance dependent on applied field. These critical fields are points where the highest steady-state peak drift velocities are achieved and being reported as 65 kV/cm, 140 kV/cm, and 450 kV/cm with corresponding peak velocities of 2.9×10^7 cm/s, 1.7×10^7 cm/s, and 1.6×10^7 cm/s for InN, GaN, and AlN, respectively. Among them InN exhibits the highest peak overshoot velocity, on the order of 10^8 cm/s at 260 kV/cm, and the longest overshoot relaxation distance, on the order of 0.8 μ m at 65 kV/cm. To optimize device performance by only minimizing the transit time over a given distance is prevented by a trade-off between the peak overshoot velocity and distance taken to achieve steady state. The upper bound for the cutoff frequency of InN- and GaN-based HFETs (heterojunction field effect transistor) benefits from larger applied fields and accompanying large velocity overshoot when the gate length is less than 0.3 μ m in GaN and 0.6 μ m in InN based devices. However, all measured cutoff frequencies are gate-length-dependent and well below these expectations, indicating that devices operate in the steady-state regime and other effects, such as real-space transfer, should also be considered. On the other hand, there is some controversy in the reports related to the onset of velocity overshoot in nitride semiconductors. For example, *Rodrigues et al.* [32.211] reported that overshoot onsets

at 10 kV/cm in InN, 20 kV/cm in GaN, and 60 kV/cm in AlN by using a theoretical model based on a nonlinear quantum kinetic theory, which compares the relation between the carriers' relaxation rate of momentum and energy.

Experimental investigations of transient transport in group III nitrides are very limited and few results are reported by using different techniques. *Wraback et al.* [32.212] employed a femtosecond time-resolved electroabsorption technique to study transient electron velocity overshoot for transport in the AlGaIn/GaN heterojunction p-i-n photodiode structures. It has been reported that electron velocity overshoot can be observable at electric fields as low as 105 kV/cm. Velocity overshoot increases with electric fields up to ≈ 320 kV/cm with a peak velocity of 7.25×10^7 cm/s relaxing within the first 0.2 ps after photoexcitation. The increase in electron transit time across the device and the decrease in peak velocity overshoot with increasing field beyond 320 kV/cm is attributed to a negative differential resistivity region of the steady-state velocity-field characteristic in this high-field range. *Collazo et al.* [32.213] used another experimental technique based on the measurement of the energy distribution of electrons which were extracted into vacuum through a semitransparent Au electrode, after their transportation through intrinsic AlN heteroepitaxial films using an electron spectrometer. They observed electron velocity overshoot as high as five times the saturation velocity and a transient length of less than 80 nm at a field of 510 kV/cm. In order to design an electronic device that is expected to operate at high power and high frequency, one should consider obtaining benefit from velocity overshoot effect in group III nitrides semiconductor heterojunctions. A systematic investigation of InN, GaN, AlN and their alloys as a function of various parameters in dynamic mode would be very beneficial for the development of higher-performance, next-generation electronic and optoelectronic devices.

32.6 Optical Properties of Nitrides

The optical properties of a semiconductor are connected with both intrinsic and extrinsic effects. Intrinsic optical transitions take place between the electrons in the conduction band and holes in the valance band, including excitonic effects due to the Coulomb interaction. Excitons are classified into free and bound excitons. In high-quality samples with low impurity concentra-

tions, the free exciton can also exhibit excited states, in addition to their ground-state transitions. Extrinsic properties are related to dopants or defects, which usually create discrete electronic states in the band gap, and therefore influence both optical absorption and emission processes. The electronic states of the bound excitons (BEs) depend strongly on the semiconductor material,

in particular its band structure. In theory, excitons could be bound to neutral or charged donors and acceptors. A basic assumption in the description of the principal bound exciton states for neutral donors and acceptors is a dominant coupling of the like particles in the BE states [32.214]. For a shallow neutral donor-bound exciton (DBE), for example, the two electrons in the BE state are assumed to pair off into a two-electron state with zero spin. The additional hole is then assumed to be weakly bound in the net hole-attractive Coulomb potential set up by this bound two-electron aggregate. Similarly, neutral shallow acceptor-bound excitons (ABE) are expected to have a two-hole state derived from the topmost valence band and one electron interaction. These two classes of bound excitons are by far the most important cases for direct-band-gap materials like group III nitrides. Other defect-related transitions could be seen in optical spectra such as free-to-bound (electron–acceptor), bound-to-bound (donor–acceptor) and so-called yellow luminescence. Several experimental techniques are used for the investigation of the optical properties of group III nitrides, including optical absorption, transmission, photoreflection, spectroscopic ellipsometry, photoluminescence, time-resolved photoluminescence, cathodoluminescence, calorimetric spectroscopy, pump-probe spectroscopy, etc. In this section, we will only present some important optical properties of GaN and available data related to AlN and InN.

32.6.1 Gallium Nitride

Free Exciton in GaN

The wurtzite GaN conduction band (Γ_7^c) is mainly constructed from the s state of gallium, whereas the valence band is mainly constructed from the p state of nitrogen. Under the influence of the crystal-field and spin-orbit interactions, the six-fold degenerate Γ_{15} level splits into a highest Γ_9^v , upper Γ_7^v , and lower Γ_7^v levels. The near-band-gap intrinsic absorption and emission spectrum is therefore expected to be dominated by transitions from these three valence bands. The related free-exciton transitions from the conduction band to these three valence bands or vice versa are usually denoted by $A \equiv \Gamma_7^c \leftrightarrow \Gamma_9^v$ (also referred to as the heavy hole), $B \equiv \Gamma_7^c \leftrightarrow \Gamma_7^v$ the upper one (also referred to as the light hole), and $C \equiv \Gamma_7^c \leftrightarrow \Gamma_7^v$ the lower one (also referred to as the crystal-field split band), respectively. The optical properties of these excitonic transitions will be discussed in some detail here. In ideal wurtzite crystals, i.e. strain-free, these three exciton states obey the following selection rules in optical one-photon processes:

Fig. 32.19 Experimental reflectance spectrum taken at 2 K (solid line) for a 2- μm GaN film grown on sapphire along with a theoretical fit using a damped-oscillator model. After [32.215]

all excitons are allowed in the σ polarization ($E \perp c$ and $k \perp c$ -axis), but the C exciton is quite weak. The C exciton is strongly allowed in the π polarization ($E \parallel c$ and $k \perp c$), however, where the B exciton is weakly observable, the A exciton is forbidden in this geometry. In the α polarization ($E \perp c$ and $k \parallel c$) all three transitions are clearly observable [32.216]. Each of these fundamental exciton states are expected to have a fine structure due both to exciton polariton longitudinal–transverse splitting and the splitting caused by the electron–hole exchange interaction, which are on the order of 1–2 meV [32.217]. Until very recently, this splitting has nearly been impossible to observe due to limitations in the spectroscopic line width of the free exciton on the order of 1 meV in the best sample so far available [32.218]. The optical spectroscopy of the intrinsic excitons can be measured by employing the low-temperature photoluminescence (PL), absorption, and/or derivative technique like photoreflectance (PR) and calorimetric absorption and reflection techniques [32.219, 220]. These measurements pave the way for the determination of exciton binding energies, exciton Bohr radii, the dielectric constant, and with the aid of the quasi-cubic model, spin–orbit and crystal-field parameters. There are several reports in the literature on reflectance studies for thick GaN epilayers [32.216, 221–224] as well as on homoepitaxial layers [32.225, 226] and bulk GaN [32.227]. Monemar et al. [32.220], who have examined numbers of thin and thick layers on various substrates, including homoepitaxial layers on GaN substrates, concluded that the A, B, and C exciton lines in GaN relaxed to an accuracy of ± 2 meV are 3.478, 3.484, and 3.502 eV, respectively, at

2 K. An example of a reflectance spectrum obtained in the α polarization is given in Fig. 32.19 for a 2- μm -thick GaN epilayer on sapphire. The corresponding excitonic transition energies were evaluated with a classical model involving a damped-oscillator transition [32.215].

Calorimetric absorption or reflection is a different experimental technique that has recently been employed to measure the fundamental exciton resonance spectra for a thick GaN epilayer grown on sapphire at 43 mK (Fig. 32.20). The values for the A, B, and C excitons agree with those quoted above for reflection measurement, apart from a small increase of about 2 meV in the case of calorimetric measurement [32.228].

A very powerful technique for studying exciton structure is photoluminescence. Figure 32.21 displays an example of a PL spectrum in the range of fundamental excitons recently taken at 2 K for an approximately strain-free thick GaN epilayer grown on sapphire by HVPE. The PL spectrum is typically dominated by strong emission related to donor-bound excitons (bound excitons will be further discussed later). At higher energies, the $n = 1$ ground states of A and B excitons

Fig. 32.20 Calorimetric absorption (CAS), reflection (CRS), and transmission (CTS) spectra of the 400- μm -thick HVPE GaN/sapphire layer ($T = 45$ mK). This sample is assumed to be nearly strain-free. In the *inset*, a fit to the reflection spectra of the FE(A) (free exciton) exciton is shown. After [32.228]

Fig. 32.21 Photoluminescence spectra at 1.8 K for a 400- μm -thick GaN grown on a sapphire substrate. The spectrum is dominated by the donor-bound exciton, but the intrinsic exciton states are also resolved at higher energies (*inset*). After [32.228]

Fig. 32.22 Photoluminescence spectrum (solid line) taken at 4.2 K for a homoepitaxial GaN layer, showing a doublet structure of the A exciton. Corresponding reflectance spectrum for the sample are also shown (dashed line). After [32.229]

are clearly observed with a less-intense C exciton, as well as the $n = 2$ excited state of the A exciton [32.230]. The splitting between the A, B, and C exciton ground states, Δ_{AB} and Δ_{AC} , are (5.5 ± 0.1) and (22.0 ± 0.1) meV. With the aid of these exciton energies, the corresponding values for the splittings

of the three top valance bands have been estimated using a quasi-cubic approximation model. Values of $\Delta_{\text{cr}} \approx 20 \pm 2 \text{ meV}$ for the crystal-field splitting and $\Delta_{\text{so}} \approx 10 \pm 2 \text{ meV}$ for the spin-orbit splitting were reported [32.220]. Edwards et al. [32.171] and Rodina et al. [32.230] have reported different values for the energy splitting parameters: $\Delta_{\text{cr}} \approx \Delta_{\text{so}} \approx 16 \pm 2 \text{ meV}$, and $\Delta_{\text{cr}} \approx 12.3 \pm 0.1 \text{ meV}$, and $\Delta_{\text{so}} \approx 18.5 \pm 0.1 \text{ meV}$, respectively.

Additionally, fine structure of exciton lines was also reported in the energy region near the band edge of GaN using various optical measurements by several groups [32.233–236]. The excitonic spectra taken at 4.2 K for homoepitaxial GaN layers, shown in Fig. 32.22, indicate that the A exciton line splits into two components about 2 meV apart, with the lowest component at about 3.477 eV. A possible interpretation is that these two components actually correspond to recombination from the lower and upper polaron branches. Similarly, Gil et al. [32.237] have also deduced the longitudinal-transverse splitting by re-

flectance line-shape fitting to the data. For each exciton, the longitudinal transverse splitting is calculated as 2.9 meV and 1.8 meV for the A and B excitons, respectively. This compares, within the experimental accuracy, with the splitting of 2.4 and 1.8 meV between the energies of the dips in the PL bands at 3.4894 and 3.4978 eV, and transverse excitons as shown in Fig. 32.22.

The values of the near-band-gap exciton energies are strongly sensitive to built-in strain, which commonly occurs when the GaN is grown on a foreign substrate with heteroepitaxy. GaN grown on sapphire substrates usually experiences a compressive strain, which in turn, increases the band gap, and hence increases in A, B, and C exciton energies and splittings, compared to the case of unstrained bulk GaN, are consistently observed. Upshifts of the A and B excitons by as much as 20 meV have been observed at 2 K, and the C exciton has been found to shift as much as 50 meV [32.222]. An example of the systematic shifts observed in reflectance data for A, B, and C excitons is shown in Fig. 32.23. On the other hand, a different situation is expected to occur for GaN growth on another widely used substrate, SiC, due to the tensile strain, which in turn is expected to lead to a decrease in the overall exciton energies (and the band

Fig. 32.23 The strain dependence of the free-exciton resonance energies in wurtzite GaN grown on sapphire substrate. The strain was obtained from the measured lattice parameter values for each sample. Theoretical modeling of the strain dependence of exciton energies are also shown. [32.231]

gap), and also a decrease in the A, B, and C splittings. As a summary, a comparison of free-exciton energies obtained from reflectance PL and other optical techniques for heteroepitaxial GaN grown by several techniques on various substrates, producing different degrees of strain, and unstrained homoepitaxy as well as bulk GaN is given in Table 32.5.

It should be pointed out that considerable variation exists between different reports in the literature [32.232, 238, 251]. The temperature dependence of the intrinsic-exciton energies is also dependent on the particular sample and local strain. Figure 32.24 presents a comparison between the temperature dependence of the exciton energies for three samples, presumably relaxed (bulk GaN), under compression (grown on sapphire) and under tension (grown on SiC). The temperature dependence of excitonic resonance (in the absence of localization) can be described by the Varshni empirical relation

$$E_g(T) = E_0(0) - \alpha T^2 / (\beta + T), \quad (32.15)$$

where $E_0(0)$ is the transition energy at 0 K, and α and β are the temperature coefficients. The free-exciton transitions are the dominating PL process at room temperature in GaN. This has been well established by PL spectral data over a wide range of temperatures for nominally undoped samples. However, the PL intensity at the position of the band gap at 300 K is considerably lower than the A exciton intensity [32.252].

Free-exciton transitions in wide-band-gap materials have a characteristic coupling to LO phonons [32.253]. As expected from the theory of LO-phonon coupling for exciton polaritons the first two replicas are strongest. The 3[−]LO and 4[−]LO replicas are also clearly observable. As predicted by theory, the characteristic temperature dependence of relative ratios of the intensities of the LO-phonon replicas is linearly proportional to the temperature and this behavior is confirmed for the A exciton for temperatures $T < 100$ K [32.248].

The binding energy of excitons determines the energy of the band gap of the material, but the strength of

the binding is also an important factor for the thermal stability of the excitons. *Chen et al.* [32.254] have calculated the binding energies as $\Delta E_A^b = \Delta E_B^b = 20$ meV for the A and B excitons and $\Delta E_C^b = 18$ meV for the C free exciton. By using the values of the effective electron and hole masses, *Chichibu et al.* [32.241] reported the calculated binding energy of the A exciton as 27 meV, which is close to the early estimation of 27.7 meV reported by *Mahler and Schroder* [32.255]. There have been very scattered experimental values reported for the free-exciton binding energies in GaN, as recently reviewed [32.256]. The scatter in the data is probably due to measurements on highly strained layers, and in some case misinterpretations of some features in the optical spectra. There is, in general, no feature at the band-edge position in the optical spectra, therefore, the exciton binding energy has to be obtained indirectly using the temperature dependence of the free-exciton transition in photoluminescence [32.240] or the position of the excited states if the positions of the excited states of the excitons are known [32.242, 243, 257]. The more recent data on both reflectance and photoluminescence (PL) reported for homoepitaxial samples appear convincing.

Fig. 32.25 Photoluminescence transients at 2 K for a GaN epilayer grown on sapphire measured at different excitation power intensity. IRS denotes the instrumental response in the experiment. [32.220]

A value of 25 meV is reported for the A exciton, and very similar values are reported for the B and C excitons [32.226, 258]. The $n = 2$ transitions are clearly resolved in these spectra, giving confidence that these results will be accurate for pure unstrained material, with a precision of about 1 meV.

The temporal behavior of excitons is of importance for emitters in that it provides a window on the dynamics of recombination processes. They should ideally be fast to be able to compete efficiently with nonradiative processes, such as multi-phonon emission and defect-related nonradiative centers. PL transient data represent an excellent tool to study both recombination rates of radiative and nonradiative processes in GaN. The temporal behavior at low excitation levels indicates processes, depending on the sample, that are as fast as about 35 ps for free excitons. Typical transients are shown in Fig. 32.25, which were obtained at different excitation intensities for a GaN epilayer grown on sapphire. Decay times at 2 K were found to vary between 60 ps and 115 ps, depending on the excitation intensity, indicating strong defect participation under these excitation intensities. The decay in luminescence intensity can more reasonably be described with a combination of a fast decay followed by a slower process with a decay time of about 300 ps at longer times. This slow process may be associated with weak localization of the free excitons, perhaps due to potential fluctuation induced by the inhomogeneous strain field.

Bound Excitons in GaN

The A, B, and C excitons discussed above represent intrinsic processes, as they do not involve pathways requiring extrinsic centers. In GaN, the neutral shallow donor-bound exciton (DBE), or I_2 , is often dominant because of the presence of donors, due to doped impurities and/or shallow donor-like defects. In samples containing acceptors, the acceptor-bound exciton (ABE), or I_1 , is observed. The recombination of bound excitons typically gives rise to sharp lines, with a photon energy characteristic for each defect. As in the free-exciton case, some fine structure is also expected in bound exciton lines, which are usually on the order of or below 1 meV for shallow donor- and acceptor-bound excitons. A characteristic phonon coupling, which can involve both lattice modes and defect-related vibrational modes, is also seen for each particular bound exciton spectrum. The photon energy region for DBE spectra is about 3.470–3.4733 eV at 2 K for strain-free GaN [32.218, 226]. Thick heteroepitaxial layers grown by HVPE give the best spectroscopic characteristic,

Fig. 32.26 Photoluminescence spectrum of a thick HVPE GaN layer showing two donor BE lines and an acceptor BE. The spectrum is upshifted by the compressive strain by about 6 meV compared with strain-free GaN. After [32.266]

with an optical line width of about 1 meV or less, as seen in Fig. 32.26. It is commonly argued that oxygen and silicon are the two most dominant residual shallow donors in GaN. In homoepitaxial GaN samples grown by MOVPE on a pretreated GaN single crystal, a narrower spectral line width down to 0.1 meV for the DBE peaked at 3.4709 eV has been reported [32.226]. In this case, in addition to unidentified sharp satellite lines on both sides of the main DBE peak, shallow DBE is the dominant line and has recently in the literature been assigned to substitutional Si donors [32.259]. Therefore, the high-energy line would then be O-related; O is known to be a typical contaminant in GaN grown by all techniques. Another high-quality MBE-grown GaN epitaxy on a GaN substrate shows at least three well-resolved peaks in the DBE region, at about 3.4709, 3.4718, and 3.4755 eV [32.260, 261]. In addition to the mostly accepted Si- and O-related shallow donor states, another donor is needed to identify the third line. It has been argued that these two levels (3.4709 and 3.4718 eV) could be attributed to exchange-split components of the same donor. Strain-splitting has also been considered in some cases. The most energetic one at 3.4755 eV is related to the B valance band involved in DBE. The localization energy for donor-bound excitons is about 6–7 meV. The corresponding binding energy of the dominating shallow donor electron has been estimated as about 35.5 meV from IR absorption data. An activation energy for electron conduction of

30–40 meV has been reported for O implanted in GaN by Pearton et al. [32.262]. Recent data from a combination of electrical and optical measurements on Si-doped GaN samples indicate that the Si donor has a binding energy of about 20 meV, while a deeper donor (35 meV) was also present, suggested to be O-related [32.151]. Monemar [32.263] estimated the binding energy of the donor electron from the two-electron satellites, which involves the radiative recombination of one electron with a hole, leaving the remaining neutral donor with a second electron in an excited $n = 2$ state. Assuming ideal effective-mass behavior, a binding energy of about

Fig. 32.27a,b Photoluminescence transients for a 400- μm -thick GaN layer (a) and for a thin strained layer (b) both grown on sapphire. After [32.266]

29 meV for the dominant donor in a 400- μm -thick HVPE GaN layer grown on sapphire has been estimated. By using the same technique for the MBE-grown GaN on a freestanding GaN template, Reshchikov et al. [32.264] determined the binding energies of two distinct shallow donors as 28.8 and 32.6 meV, which were attributed to Si and O, respectively. These combined data also provide strong evidence for a tentative identification of the 3.4709 eV DBE as being due to the neutral silicon donor. It is likely that the often-observed second DBE peak at 3.4718 eV in unstrained GaN is then related to the O donor, but this remains to be proven. In his review, Viswanath [32.265] listed commonly observed and reported peak positions and localization energies of DBE in GaN grown by various growth techniques on different substrates under compressive or tensile strain.

Another important property of DBEs is the recombination dynamics. The low-temperature decay rate for the DBE PL line gives the radiative lifetime of the DBE. Figure 32.27 shows photoluminescence transients measurements for a thick HVPE-grown GaN layer ($\approx 100\ \mu\text{m}$), with low dislocation density (in the $10^7\ \text{cm}^{-2}$ range), as well as for a thin strained layer grown on sapphire. In HVPE-grown thick layers, a low intensity decay time of about 200 ps is observed at 2 K, which is a typical radiative lifetime for DBEs related to shallow neutral donors. In thin strained heteroepitaxial layers with a higher defect density, a shorter lifetime is observed [32.267–269], indicating the effect of excitation transfer from the DBE to lower-energy states before the radiative recombination takes place. Similarly, homoepitaxial GaN layers also often show a fast DBE decay at low excitation density, due to excitation transfer to point defects [32.220]. A slow component, which is indicative of a slower radiative process overlapping the DBE transition, is also observed in the DBE decay dynamics [32.220, 257]. A recent observation on the DBE decay time for n-type GaN layers grown on SiC substrates indicated a clear trend versus the energy position of the DBE line, which in turn correlated with the strain in the layer. The biaxial strain in the GaN layer strongly affects the top valence band states, which in turn is reflected in the DBE wavefunction [32.258], affecting the oscillator strength and hence the observed radiative lifetime [32.227].

In the energy region below the principle DBE line there is usually a rich spectrum of bound excitons assumed to be acceptor-related. However, the situation for acceptor BEs (ABE or I_1) in GaN is somewhat less clear than for the donors. The most prominent neutral ABE is found at about 3.466 eV in strain-free GaN and

Fig. 32.28 Low-temperature PL spectrum (solid line) of a HVPE GaN layer shown on a semi-logarithmic scale. The reflectivity spectrum (dashed line) of the same sample taken at normal incidence geometry is plotted on a linear scale. After [32.266]

attributed to the exciton bound to a shallow acceptor, probably Mg_{Ga} (Fig. 32.28). Furthermore, this peak has been found to be dominant in slightly Mg-doped GaN samples [32.270–272]. An alternative interpretation of this BE line, which is related to charged donor-bound excitons, has recently been proposed by several groups [32.273–276]. The other main peak at about 3.455 eV has been attributed to Zn, but this is not yet justified. The broader peak at 3.44 eV is probably due to a low-energy acoustic-phonon wing connected to the main peak at 3.455 eV, which is very characteristic for ABEs [32.277, 278]. Also, phonon replicas are seen in the spectrum, indicating a rather strong LO-phonon coupling, much stronger than for the DBE. Since most experiments with doped samples up to now have been performed on heteroepitaxial material, there is a difficulty in determining the peaks, where the ABE peak position strongly depends on the strain. A binding energy of 19 meV was reported for Mg-doped GaN with an A exciton position at 3.499 eV and the Mg-related ABE at 3.480 eV at 2 K [32.279] indicating that ABEs, being deeper, may not follow a constant distance to the A free-exciton position (as in the case for the most shallow DBEs) in strained layers. In unstrained samples, like Mg-doped homoepitaxial GaN epilayers, the binding energy is found to be 11–12 meV [32.226, 280, 281], under the assumption that the 3.466 eV BE is Mg-related.

An additional deeper, probably acceptor-related, BE PL line in GaN is also observed at 3.461 eV (a doublet structure) [32.269]. However, due to the strain-induced shift in an upwards direction in the spectrum, this might be the same ABE as observed in some homoepitaxial layers at 3.455 eV with a line width of about 95 μeV [32.226], indicating a BE binding energy of about 21 meV. Although the identity of this acceptor has not been established, it is close to the position observed from the dominant ABE in Zn-doped samples, if strain shifts are considered [32.279]. Therefore, it might be due to residual Zn acceptors, present as contaminants in many samples, but this is not certain.

In contrast to the case of DBEs, the decay curves are usually clean exponential for the ABEs, as seen in Fig. 32.27b, and presumably reflect the radiative lifetimes of the BEs at the lowest temperatures, before thermalization occurs. The observed value of radiative lifetimes is about 0.7 ns for the shallowest ABE peaked at 3.466 eV, as compared to the much longer time, 3.6 ns, for the deeper acceptors with an ABE peak in the range 3.455–3.46 eV [32.269]. This corresponds to an oscillator strength of the order of 1, very similar to the shallow acceptor BEs in CdS [32.282]. To distinguish band-edge exciton features, the temperature-dependent luminescence experiment allows one to discriminate free versus donor-bound or acceptor-bound excitons. With increasing temperature, all peaks related to the bound excitons quench due to thermal delocalization, while the quenching of the free excitons is negligible up to 50 K. Excitons bound to the donor quench faster than excitons bound to the acceptor, which is consistent with their binding energies [32.264].

Donor–Acceptor Transitions in GaN

Due to compensation in semiconductors both ionized donors and acceptors could be present in the material. Nonequilibrium carriers generated by optical excitation can be trapped at the donor and acceptor sites, causing them to be neutral. While reaching equilibrium, they can relax their excess energies through radiative recombination of some electrons on the neutral donor sites with holes on the neutral acceptor sites, a process termed donor–acceptor pair (DAP) transition. DAP spectra are very common examples of radiative recombination in GaN. A no-phonon replica is observed at about 3.26 eV at low temperature, with well-resolved LO-phonon replicas towards the lower energy [32.283–285]. The temperature dependence of the spectrum reveals the evolution from a DAP pair spectrum at low temperature to a free-to-bound conduction-band-to-acceptor transition

peaked 3.273 eV at higher temperature (120 K) due to thermal ionization of the shallow donors ($E_D \approx 29$ meV) into the conduction band. At intermediate temperatures, both processes may be resolved. The acceptor binding energy has also been estimated as about 230 meV from this measurement. The identity of this acceptor is not clear, but it has been suggested that it is due to carbon acceptor substitution on nitrogen sites [32.285], while others claimed that it is simply related to Mg acceptors on Ga sites. PL of Mg-doped wurtzite GaN has been studied and showed the DAP transition at 3.26 eV at 4.2 K along with its LO-phonon replicas. At higher Mg concentrations, the PL is dominated by a deep-level broad band with its peak at 2.95 eV. The blue emission is clearly observed for Mg concentrations of 5×10^{19} – $2 \times 10^{20} \text{ cm}^{-3}$. In addition to the peak position for the identification of this transition, further confirmation is provided by a blue shift at a rate of about 2–3 meV per decade of intensity as the excitation intensity increased [32.286].

The behavior of radiative lifetimes and time-resolved spectra has been used as a further test for the DAP transition. It has been observed that carrier dynamics of 3.21 and 2.95 eV emissions in relatively heavily doped Mg-doped p-type GaN epilayers [32.287] exhibited nonexponential lifetimes on the sub-nanoseconds scale, comparable to that of a band-to-impurity transition in a highly n-type GaN epilayer involving a donor and the valence band [32.242, 288]. Smith et al. [32.287] observed the temporal behavior of the 3.21-eV emission band, which follows a power law with an exponent greater than 1.0 at longer delay times. All these indications lead one to conclude that the 3.21-eV line corresponds to the conduction-band-to-impurity transition involving shallow Mg impurities, while that at about 2.95 eV is attributed to the conduction-band-to-impurity transitions involving deep-level centers (or complexes).

Defect-Related Transitions in GaN: Yellow Luminescence (YL)

A broad PL band peaking at 2.2 ± 0.1 eV, so-called yellow emission, is almost systematically observed in undoped or n-GaN. As studied extensively by Ogino and Aoki [32.289] and more recently by others [32.290–292] there seems to be agreement that transitions from the conduction band or a shallow donor to a deep acceptor are responsible for this band. Another interpretation of the yellow band as being due to transitions between a deep donor and a shallow acceptor was also proposed to explain the results of magnetic-resonance experiments [32.293]. The exact position of this band

and its line width differ slightly in numerous publications. The nature of the deep donor has not been established, but several candidates such as the nitrogen vacancy [32.294], gallium vacancy or its complexes with a shallow donor [32.291, 292] or carbon [32.289, 295] have been suggested. The issue of whether the YL is related to a point defect or to a distribution of states in the gap is still an open question. *Shalish et al.* [32.296] invoked a broad distribution of acceptor-like surface states to account for the YL band. A redshift of the YL band with decreasing energy of the below-gap excitation may also indicate that the broadening of the YL band is due to emission from several closely spaced traps [32.297]. On the other hand, the temperature dependence of the bandwidth and the photoluminescence excitation spectrum have been quantitatively explained by using a configuration-coordinate model that attributes the YL band to a point defect with strong electron–phonon interaction [32.289, 298]. Theoretical calculations predict a low formation energy and the deep acceptor levels for the isolated Ga vacancy, possibly as a complex with a shallow donor impurity such as Si and O ($V_{Ga}Si_{Ga}$ and $V_{Ga}O_N$) [32.291, 292]. It has also been demonstrated that the formation of these defects is much more favorable at a threading-edge dislocation [32.299]. The intensity of the YL band has been found to correlate with dislocation-related defects [32.300].

The transient PL decay times of the YL has been investigated by different research groups. *Hofmann et al.* [32.301] and *Korotkov et al.* [32.302] reported rather long and nonexponential decay of the YL in the range 0.1–100 μ s at low temperatures, which was quantitatively described in the Thomas–Hopfield model [32.303] of the donor–acceptor pair (DAP) recombination. A very long-lived emission decay time of about 300 ms at 10 K has been observed by *Seitz et al.* [32.304]. In contrast, very fast decay times of about 1 ns at 2 K and 20 ps at room temperature have been reported and related to a strong contribution from free-to-bound transitions and DAP recombination by *Godlewski et al.* [32.305] and *Haag et al.* [32.306], respectively. *Reshchikov et al.* [32.307] performed time-dependent PL of YL in freestanding high-quality GaN templates grown by HVPE, which led them to conclude that, at temperatures below 40 K, the time decay of the 2.4 eV yellow peak is nonexponential and can be explained in the framework of the Thomas–Hopfield model for DAP-type recombination involving shallow donors. At elevated temperatures, the decay becomes exponential with two components, leading to the suggestion that

the transitions from the conduction band to two deep acceptors are involved.

32.6.2 Aluminium Nitride

The optical properties of AlN have been investigated in many forms, including powders, sintered ceramics, polycrystals and single-crystal samples. Since an AlN lattice has a very large affinity to oxygen dissolution, oxygen contamination is hard to eliminate in AlN, in which optical properties are influenced by oxygen-related defects. Some oxygen is dissolved in the AlN lattice while the remainder forms an oxide coating on the surface of each powder grain.

AlN doped with oxygen was found to emit a series of broad luminescence bands at near-ultraviolet frequencies at room temperature, no matter whether the sample was powdered, single crystal, or sintered ceramic. In an early study of the luminescence properties, *Pacesova and Jastrabik* [32.308] observed two broad emission lines centered near 3.0 and 4.2 eV, more than 0.5 eV wide, for samples contaminated with 1–6% oxygen under steady-state excitation. *Youngman and Harris* [32.309] and *Harris et al.* [32.310] found broad peaks centered at 2.7 and 3.8 eV in large single-crystal AlN with an oxygen content of 380 ppm. Oxygen-related luminescence spectra in AlN are very sensitive to sample preparation, particularly oxygen-impurity content. They observed an emission-peak shift in the PL spectra and a drastic increase in luminescence intensity below a critical oxygen content of 0.75%. Others reported different emission peaks for different forms of AlN samples with various oxygen contents. A microscopic model explaining the results was proposed by *Harris et al.* [32.310] and supported by the study of *Katsikini et al.* [32.311] and *Pastrnak et al.* [32.312]. Below the critical concentration, oxygen substitutes into nitrogen sites (O_N) with subsequent formation of Al atom vacancies (V_{Al}), while at higher oxygen content a new defect based on octahedrally coordinated Al forms.

Besides native oxygen defects or intentionally oxygen-doped AlN, other impurities that have been widely investigated are manganese and, more recently, rare-earth metals, such as erbium. In an early study, *Karel* and coworkers [32.313] reported a number of sharp emission peaks in the visible region from Mn-doped AlN. These peaks are interpreted as arising from phonon emission, in all likelihood due to localized Mn-ion vibration, associated with electronic transitions experienced by Mn^{4+} ions located at Al sites. This work was further extended by *Karel* and

Mares [32.314] and Archangelskii et al. [32.315], who observed a red band emission (600 nm) with Mn^{4+} and a green band (515 nm) with Mn^{2+} . Recently, particular attention has been paid to Er-doped AlN due to the observed strong photoluminescence at 1.54 μm , which is important for optical-fiber communication systems. In rare-earth atoms, the luminescence transition comes from the core electrons falling energetically from excited states to the ground states. For example, Er-doped AlN gives a luminescence due to transitions between the weak crystal-field-split levels of $\text{Er}^{3+}I_{13/2}$ and $^4I_{15/2}$ multiplets [32.316–318]. Pearton et al. [32.319] reported luminescence enhancement in AlN(Er) samples treated in a hydrogen plasma by passivating the defects in AlN. This increase shows no quenching on heating the sample up to 300 °C. Due to its wide band gap the 1.54- μm luminescence is more stable in AlN than in GaN.

In recent work, band-edge emission of high-quality AlN grown by MOCVD on sapphire substrate has been investigated by Li et al. [32.320]. Band-edge emission lines at 5.960 and 6.033 eV have been observed at room temperature and 10 K, respectively, as shown in Fig. 32.29. The peak integrated emission intensity of the deep-impurity-related emission centered at around 3.2 and 4.2 eV is only about 1% and 3%, respectively, of that of the band-edge transition at room temperature. The PL emission properties of AlN have been compared with those of GaN and it was shown that the optical quality as well as the quantum efficiency of AlN epilayers is as good as that of GaN. The same group [32.322] has also studied deep UV picosecond time-resolved photoluminescence spectroscopy to investigate the observed optical transition in steady-state PL measurements. Two PL emission lines at 6.015 and 6.033 eV were attributed to donor-bound exciton and

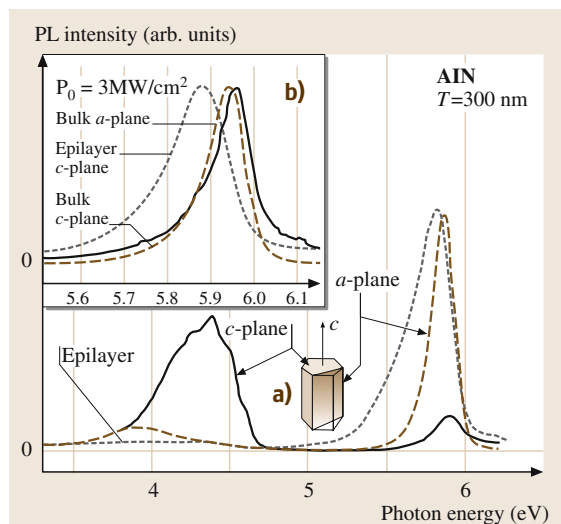

Fig. 32.30 (a) PL spectra of single-crystal AlN for A- and C-planes and AlN epilayers at room temperature under an excitation power density of 1 MW/cm². Inset (b) shows wurtzite-type crystal c-axes, C-plane, and A-plane. Inset shows room-temperature near-band emission spectra of various AlN samples under very high excitation. After [32.321]

free-exciton transitions, respectively, from which the binding energy of the donor-bound excitons in AlN epilayers was determined to be around 16 meV.

Kuokstis et al. [32.321] reported similar results by employing temperature-dependent PL measurements for A-plane and C-plane bulk single crystals and MOCVD-grown epitaxial layers on sapphire. The spectra consisted of a long wave band probably from an oxygen-related deep-level transition as discussed above and an intense

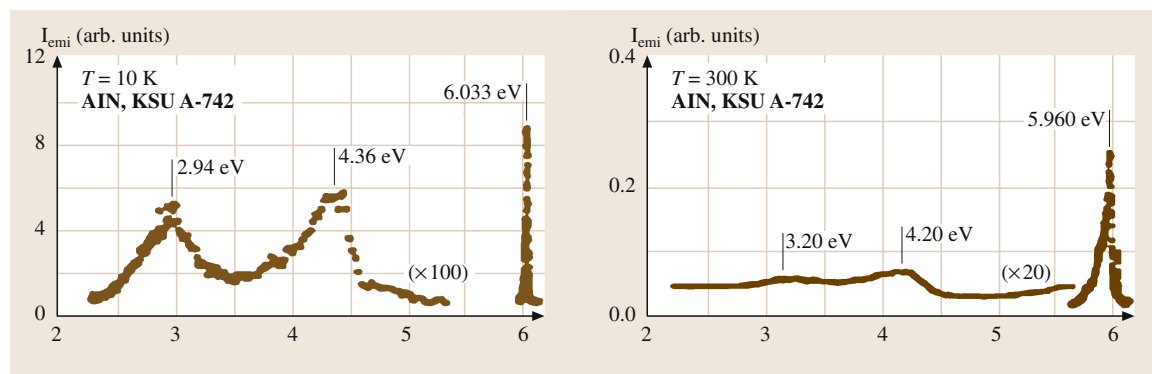

Fig. 32.29a,b PL spectra of AlN epilayers measured (a) at 10 K and (b) at 300 K. The spectra cover a broad spectral range from 2.2 to 6.2 eV. After [32.320]

near-band emission, as seen in Fig. 32.30. The near-band emissions were attributed to processes involving free excitons at 6.065 eV and their LO-phonon (≈ 5.066 eV) replicas at high temperatures and the bound excitons at 6.034 eV at low temperatures. These results, together with other well-known physical properties of AlN, may considerably expand future prospects for the application of group III nitride materials.

Time-resolved PL measurements revealed that the recombination lifetimes were around 80 ps for bound excitons and 50 ps for free excitons [32.322]. A free-exciton binding energy of 80 meV was also deduced from the temperature dependencies of both the free-exciton radiative decay time and emission intensity.

On the other hand, optical reflectance (OR) measurements [32.323] exhibited distinct reflectance anomalies at photon energies just above the multiple-internal-reflection fringes, and the spectral line shape was fitted considering A, B, and C exciton transitions. The fit gave values for the A and B excitons at 0 K of 6.211 and 6.266 eV, giving a crystal-field splitting (Δ_{cr}) of approximately 55 meV. The AlN film exhibited an excitonic emission even at 300 K, which is due to the small Bohr radius of the excitons and the large longitudinal optical-phonon energies.

Cathodoluminescence and electroluminescence emission properties of AlN have also been investigated by several groups. Rutz [32.177] reported a broad near-UV band in the electroluminescence spectra, extending from 215 nm into the blue end of the visible region. Several peaks or humps between 2.71 and 3.53 eV, which were attributed to nitrogen vacancies, interstitial Al impurities, and oxygen impurities or defects, were observed in cathodoluminescence measurements for epitaxial AlN films grown on C-plane sapphire [32.324]. In the investigation of Youngman and Harris, 4.64-eV photons were used specifically to explore the below-band transitions such as the peak near 4 eV. Their investigation showed a blue shift with increased O concentration in the peak in question. Hossian et al. [32.325] and Tang et al. [32.326] measured the cathodoluminescence at 300, 77, and 4.2 K for undoped AlN thin films grown on sapphire and SiC by LP-MOCVD (low pressure). From these samples, a strong luminescence peak surrounded by two weaker peaks in the near band-edge region, near 6 eV, was observed. For AlN on sapphire, this near-band-edge transition can be further resolved into three peaks at 6.11, 5.92, and 5.82 eV. They believe that these two peaks are due to excitonic transition because of their exciton-like temperature behavior, i. e. the energy position of these peaks increases and the

line width becomes narrower as the temperature is decreased. Recently, Shishkin et al. [32.327] has also observed a sharp, strong near-band-edge peak at 5.99 eV, which was tentatively assigned to the optical recombination of a donor-bound exciton, accompanied by weak one- and two-longitudinal optical-phonon replicas in the cathodoluminescence spectrum of a 1.25- μm -thick RMBE-grown (reactive molecular beam epitaxy) AlN film on C-plane sapphire.

Not much data are available on the temperature dependence of the optical band gap of AlN. Guo and Yoshida [32.328] investigated the variation of the band gap with temperature in AlN crystalline films. The band-gap energy increases linearly from room temperature down to about 150 K with a temperature coefficient of 0.55 meV/K. Another work was carried out by Kuokstis et al. [32.321] and similar temperature behavior was observed for single-crystal C-plane AlN with a temperature coefficient of 0.53 meV/K between 150 and 300 K (Fig. 32.31). These two observations are close to each other and also close to the value reported by Tang et al. [32.326] (0.51 meV/K). However, below 150 K, in all measurements, a new structure starts to form, where the band gap does not change linearly with temperature and has a very small temperature coefficient, which is unusual for semiconductors.

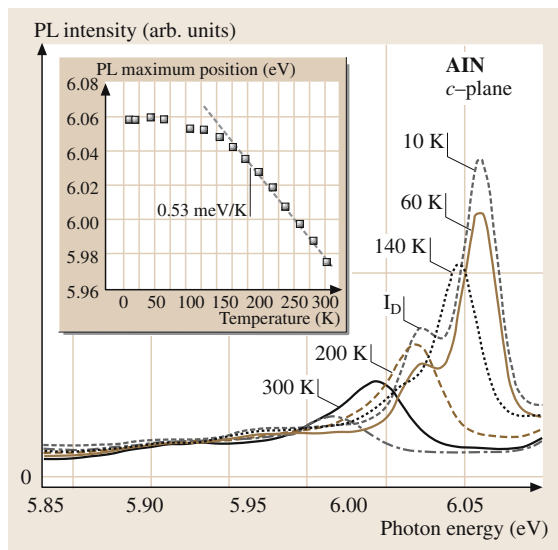

Fig. 32.31 Single-crystal AlN C-plane PL spectra at different temperatures. B denotes the free-exciton line, whereas I_D marks the bound-exciton line. The inset shows the dependence of the exciton line position on temperature. After [32.321]

In the case of absorption, the absorption coefficient in the near band edge was measured by using straightforward optical transmission and reflection experiments. In early studies, *Yim et al.* [32.174] characterized AlN by optical absorption and determined the room-temperature band gap to be direct with a value of 6.2 eV. *Perry and Rutz* [32.329] performed temperature-dependent optical absorption on a $1 \times 1 \text{ cm}^2$ epitaxial single-crystal AlN sample, measuring a band gap of 6.28 eV at 5 K compared to their room-temperature value of 6.2 eV, resulting from a straight-line fit. Several groups have reported comparable values whereas others have produced questionable values considerably below 6.2 eV, probably due to oxygen contamination or nonstoichiometry. In addition to the band-edge absorption, a much lower energy absorption peak at 2.86 eV (although some variation in the peak position has been recorded from 2.8 to 2.9 eV) is likely to be due to nitrogen vacancies or nonstoichiometry, as proposed by *Cox et al.* [32.173]. *Yim and Paff* [32.101] also observed a broad emission-spectrum range of 2–3 eV with a peak at about 2.8 eV. This peak does not correlate with the presence of oxygen. The oxygen absorption region lies between 3.5 eV and 5.2 eV, as originally found by *Pastrnak and Roskovicova* [32.330]. The exact position of this particular peak appears to change with the oxygen content from 4.3 eV at low oxygen levels to 4.8 eV at high oxygen levels.

Fig. 32.32 PL spectra at 8.5 and 100 K of InN films grown on Si substrate. After [32.331]

Measurements of the refractive index of AlN have been carried out in amorphous, polycrystalline, and single-crystal epitaxial thin films [32.332–335]. The values of the refractive index are in the range $n = 1.9$ – 2.34 with a generally accepted value of $n = 2.15 \pm 0.05$ at visible wavelengths. These values are found to increase with increasing structural order, varying between 1.8 to 1.9 for amorphous films, 1.9 to 2.1 for polycrystalline films, and 2.1 to 2.2 for single-crystal epitaxial films. The spectral dependence and the polarization dependence of the index of refraction have been measured and showed a near-constant refractive index in the wavelength range 400–600 nm. The reported refractive index generally agrees with low- and high-frequency dielectric constants determined from infrared measurements. In the long-wavelength range, the low-frequency dielectric constant of AlN (ϵ_0) lies in the range 8.5–9.1 [32.336,337], and most of the values fall within the range 8.5 ± 0.2 , while the high-frequency dielectric constant (ϵ_∞) is in the range 4.6–4.8 [32.98,338].

32.6.3 Indium Nitride

Among the group III nitrides, InN is not very well investigated. The band gap has been frequently measured by transmission experiments. In early studies, due to the large background electron concentrations of the samples and their low crystalline quality, the excitonic features, neither in the absorption spectra nor in the band-edge photoluminescence spectra, had been observed. However, a number of groups have performed optical measurements on InN [32.339–342]. Early experimental studies suggested that the band gap of wurtzite InN ranges from 1.7–2.07 eV at room temperature. Table 32.1 lists some experimental determinations of the InN band gap. They were estimated from the absorption spectra, which can lead to an overestimation of the band gap if the sample quality is poor or if the sample is highly doped. Despite this, the value of 1.89 eV for the InN band gap obtained by *Tansley and Foley* [32.343] is widely cited in the literature. They explained this experimental scatter by considering residual electron concentration (which changes the band gap of the semiconductor, as discussed before) and attributed this variation to the combined effect of band-tailing and band-filling. The value of 1.89 eV is often used as an end-point value to interpret experimentally measured composition dependence of the band gap of InN alloys [32.344]. A few studies of the inter-band optical absorption performed on InN thin films deposited by sputtering techniques [32.343] and

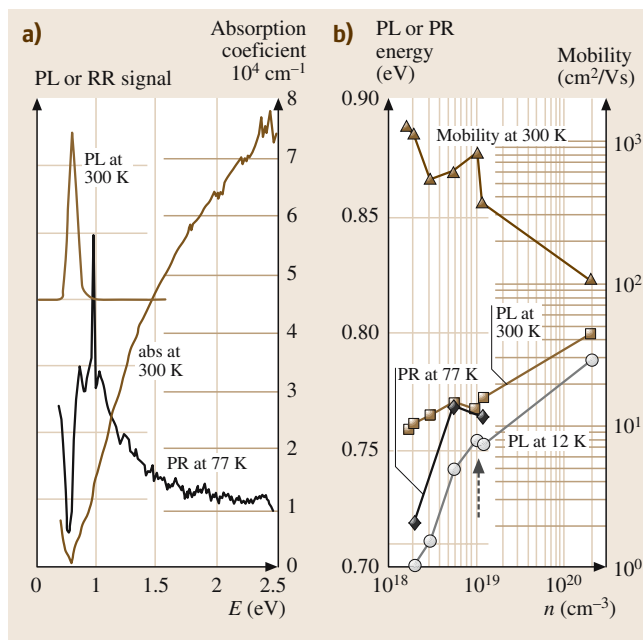

Fig. 32.33 (a) Optical absorption (300 K), PL (300 K), and PR (77 K) spectra of a typical InN sample. This sample is undoped with a room-temperature electron concentration of $5.48 \times 10^{18} \text{ cm}^{-3}$. The spike on the PR spectrum at 0.97 eV is an artifact due to the light source used in the PR measurement. (b) Room-temperature mobility, PL peak energy (300 and 12 K), and the critical energy determined by PR (77 K) as a function of free-electron concentration. After [32.349]

MOCVD [32.328] were found consistent with a fundamental energy gap of about 2 eV. Recent progress of growth techniques using molecular-beam epitaxy has led to improved InN samples, which show photoluminescence as well as a clear absorption edge. Yodo et al. [32.331] observed weak photoluminescence peaks with energies in the range 1.81–2.16 eV on InN grown on Si substrates (Fig. 32.32). However, in one such case, an emission centered at 1.86 eV at a temperature below 20 K was seen, while the reflectance measurement shows a strong plasma reflection at 0.7 eV. Another branch of studies show that in improved InN films strong photoluminescence transitions at energies around 1 eV appear [32.345–348]. These new measurements have challenged the previous widely accepted band-gap value and suggest that the actual fundamental band gap of InN is much smaller, between 0.7 and 1.1 eV. The real band gap of InN is still under investigation and undetermined.

Figure 32.33 shows the room-temperature electron mobility, the peak energy of PL, and the transition energy

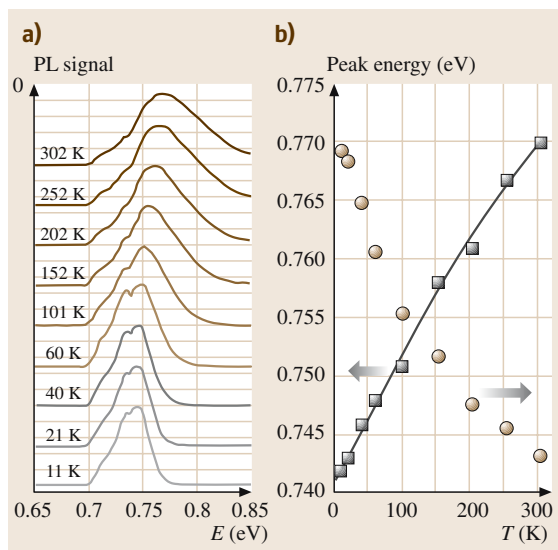

Fig. 32.34 (a) PL spectra as a function of temperature for the sample shown in Fig. 32.20a. PL spectra are normalized to a constant peak height. (b) PL peak energy and PL integrated intensity (log scale) as a function of temperature. The line through the peak energy data is a guide to the eye. After [32.349]

determined by PR as functions of electron concentration. The transition energies increase with increasing free-electron concentration, indicating that the transitions from higher-energy occupied states in the conduction band contribute significantly to the PL spectrum. The absorption coefficient increases gradually with increasing photon energy, and at the photon energy of 1 eV it reaches a value of more than 10^4 cm^{-1} . This high value is consistent with inter-band absorption in semiconductors. Moreover, the integrated PL intensity increased linearly with excitation intensity over three orders of magnitude, lending more credence to the concept that the observed nonsaturable peak is related to the fundamental inter-band transitions. The free-electron concentration in this sample was measured by the Hall effect to be $5.48 \times 10^{18} \text{ cm}^{-3}$, which also shows intense room-temperature luminescence at energies close to the optical absorption edge. Additionally, the 77-K photo reflectance (PR) spectrum exhibits a transition feature at 0.8 eV with a shape characteristic for direct-gap inter-band transitions. Consistent with the absorption data, no discernible change in the PR signal near 1.9 eV is seen. The simultaneous observations of the absorption edge, PL, and PR features at nearly the same energy indicate that this energy position of $\approx 0.78 \text{ eV}$ led Wu

et al. [32.349] to argue that this is the fundamental band gap of InN. This value is very close to the fundamental gap for InN reported by Davydov et al. [32.345].

A few groups [32.350, 351] have reported the temperature dependence of the band gap of InN, and indicated a band-gap temperature coefficient of $1.3\text{--}1.8 \times 10^{-4}$ eV/K at room temperature by using $E_g(300\text{ K}) = 1.89$ eV. The temperature dependence of PL spectra of recently investigated InN samples indicated a lower band-gap energy of 0.7 eV, as shown in Fig. 32.34. There is a small blue shift (nearly linear at 0.1 meV/K) observed in the peak energy position of the temperature-dependent PL. In addition to that, the integrated intensity of the PL decreases by ≈ 20 times as the temperature is increased from 11 K to room temperature. The data in Fig. 32.34a also show a considerable increase in the line width of the PL spectra. The full width at half maximum increases from 35 to 70 meV when the temperature increases from 11 K to room temperature.

32.7 Properties of Nitride Alloys

Many important GaN-based devices involve heterostructures to achieve improved device performance. Ternary alloys of wurtzite polytypes of GaN, AlN, and InN have been obtained in continuous alloy systems whose direct band gap ranges from ≈ 0.8 eV for InN to 6.1 eV for AlN. Many of these properties, such as the energy band gap, effective masses of the electrons and holes, and the dielectric constant, are dependent on the alloy composition. AlN and GaN are reasonably well lattice-matched (3.9%) and, owing to the large band-gap difference between GaN and AlN, for many devices only small amounts of AlN are needed in the GaN lattice to provide sufficient carrier and optical field confinement. The compositional dependence of the lattice constant, the direct energy gap, electrical and cathodoluminescence (CL) properties of the AlGaIn alloys were measured [32.358]. In general, the compositional dependence of the optical band gap of ternary alloys can be predicted by the following empirical expression;

$$E_g(x) = xE_g(\text{AlN}) + (1-x)E_g(\text{GaN}) - x(1-x)b, \quad (32.16)$$

where $E_g(\text{AlN})$, $E_g(\text{GaN})$ are the optical band gap of AlN and GaN, respectively, and x and b are the AlN molar fraction and bowing parameter, respectively. In order to determine this relation precise characterization of both the band gap and alloy composition is important. Wide dispersion in the bowing parameters ranging from

Therefore, they concluded that there is no significant shift of the PL spectra, as the temperature-induced line broadening can easily account for the observed small upward shift of the PL line maximum.

In the transparency region, the refractive index was measured using the interference spectrum observed in reflectivity or absorption [32.352, 353]. In the visible and UV region ($E > 2$ eV) optical constants were determined from reflectivity or spectroscopic ellipsometry [32.354, 355]. Although the most frequently quoted value for the static dielectric constant is $\epsilon_0 = 15.3$, the values reported for the high-frequency dielectric constant are scattered between 6.6 and 8.4, as well as the refractive index measured in the vicinity of the band gap. Tyagai et al. [32.356] were able to estimate an effective mass of $m^*_e = 0.11 m_0$ and an index of refraction $n = 3.05 \pm 0.05$ in the vicinity of the band gap. The long-wavelength limit of the refractive index was reported to be 2.88 ± 0.15 .

-0.8 eV (upward bowing) to $+2.6$ eV (downward bowing) has been reported [32.359–364]. Yun et al. [32.357]

Fig. 32.35 Experimental data for the energy band gap of AlGaIn ($0 \leq x \leq 1$) plotted as a function of Al composition (solid circle), and the least-squares fit (solid line), giving a bowing parameter of $b = 1.0$ eV. The dashed line shows the case of zero bowing. As the quality of the near-50:50 alloy layers get better, giving rise to sharper X-ray and PR data, smaller bowing parameters may ensue. Already, bowing parameters as low as 0.7 have been reported. After [32.357]

revisited the bowing parameter using X-ray and analytical techniques, such as secondary-ion mass spectroscopy (SIMS) and Rutherford back-scattering (RBS), for composition determination, reflectance and absorption for band-gap determination. The results of this study are depicted in Fig. 32.35 in the form of AlGa_xN band gap versus composition along with a least-square fit to the data, solid circles, yields a bowing parameter of $b = 1.0$ eV for the entire range of alloy compositions. Widening the X-ray diffraction peaks for alloy composition around the midway point has been attributed to be a most likely source of error in determining the bowing parameter. On the other hand, the validity of the characterization techniques used in determination the optical properties of AlGa_xN alloys is deeply affected by the material crystalline quality and purity.

As far as the electrical and doping issues are concerned, Hall measurement for n-Al_{0.09}Ga_{0.91}N demonstrated a carrier concentration of $5 \times 10^{18} \text{ cm}^{-3}$ and a mobility of $35 \text{ cm}^2/\text{Vs}$ at room temperature [32.365]. Other Hall measurements [32.366] on Mg-doped p-Al_{0.08}Ga_{0.92}N grown by OMVPE (organometallic vapor phase epitaxy) addressed the temperature dependence of the mobility. They indicate that the hole mobility decreases with increasing temperature, reaching a value of about $9 \text{ cm}^2/\text{Vs}$ for a doping density of $1.48 \times 10^{19} \text{ cm}^{-3}$. This low mobility is ascribed to a high carrier concentration and the inter-grain scattering present in the samples. While the lattice constant was studied, it was observed to be almost linearly dependent on the AlN mole fraction in AlGa_xN.

Until recently the resistivity of unintentionally doped AlGa_xN was believed to increase so rapidly with increasing AlN mole fraction that AlGa_xN became almost insulating for AlN mole fractions exceeding 20%. As the AlN mole fraction increased from 0 to 30%, the n-type carrier concentration dropped from 10^{20} to 10^{17} cm^{-3} , and the mobility increased from 10 to $30 \text{ cm}^2/\text{Vs}$. An increase in the native-defect ionization energies with increasing AlN may possibly be responsible for this variation. The respond of the dopant atoms such as Si and Mg to the variation of the AlN mole fraction in AlGa_xN has not been well understood yet. It was suggested that dopant atom moves deeper into the forbidden energy band gap as the AlN mole fraction increases. For example, Hall-effect measurements show that the activation energy of Si donor increases linearly from 0.02 eV in GaN to 0.32 eV in AlN [32.367]. However, devices such as lasers, which depend critically on the overall device series resistance and require low-resistivity p-type material, will

probably be restricted by the ability to dope high-mole-fraction AlGa_xN. Fortunately, the emergence of InGa_xN coupled with the fact that good optical-field confinement can be obtained with low-AlN-mole-fraction AlGa_xN mitigate this problem enormously, and the potential is very bright for laser development in this material system.

The ternary InGa_xN is used mostly for quantum wells, strained to some extent depending on the level of phase segregation, etc., in the active regions of LEDs and lasers, which can emit in the violet or blue wavelength range. Needless to say, high-efficiency blue and green LEDs utilizing InGa_xN active layers are commercially available. However, added complexities such as phase separation and other inhomogeneities due to the large disparity between Ga and In make the determination of the band gap of InGa_xN versus composition a very difficult task, not to mention the controversy regarding the band gap of InN. The compositional dependence of the InGa_xN band gap is a crucial parameter in the design of any heterostructure utilizing this material. Similarly to the case of AlGa_xN, the energy band gap of In_xGa_{1-x}N over $0 < x < 1$ can be expressed by (32.16) using the band gap of InN instead of AlN band gap. When a bandgap of ≈ 1.9 eV for InN is assumed as the end-point value for InN in regard to the InGa_xN ternary, large and/or more than one bowing parameters are required to fit the compositional dependence of the band-gap energy. An earlier investigation of InGa_xN bowing parameter for alloys with small concentrations of InN [32.368] led to a bowing parameter of 1.0, which is in disagreement with 3.2 reported by *Amano* et al. [32.369], who also took into consideration strain and piezoelectric fields and arrived at a value of 3.2. A bowing parameter of 2.5 eV was obtained from optical absorption measurements and a value of 4.4 eV was obtained from the position of the emission peak [32.370]. *Nagatomo* et al. [32.371] noted that the In_xGa_{1-x}N lattice constant varies linearly with the In mole fraction up to at least $x = 0.42$, but it violates Vegard's law for $x > 0.42$, which may be caused by erroneous determination of the composition and is very relevant the problem at hand. Recent observations indicated that these alloys show strong infrared PL signal as expected from an InN band gap of ≈ 0.8 eV, extending the emission spectrum of the In_{1-x}Ga_xN system to near infrared. [32.347] revisited the dependence of the InGa_xN band gap on composition by considering ≈ 0.8 eV for the band gap of the end binary InN. Figure 32.36 shows the compositional dependence of the band gap of InGa_xN, determined by photomodu-

Fig. 32.36 PL peak energy and band gap determined by optical absorption as a function of composition, including previously reported data for the Ga-rich end of the ternary which is not as affected by the large InN band gap previously used. The *solid curve* shows the fit to the band gap energies (abs and PT) using a bowing parameter $b = 1.43$ eV. The *dashed curve* is the fit to the band-gap energies on the Ga-rich side assuming a band gap of 1.9 eV for InN. *Inset*: PL peak energy plotted against absorption edge energy. The *solid line* is a least-squares fit to experimental data on the Ga-rich side. The *dashed straight line* shows the relation when the Stokes shift is zero. After [32.245] and courtesy of Wlodek Walukiewicz

lated transmission [32.372] optical absorption [32.373] measurements, as a function of GaN fraction. The compositional dependence of the band gap in the entire compositional range can also be fit by a bowing parameter of $b = 1.43$ eV. Also shown in the figure with a dashed line is the fit to the empirical expression using an energy of 1.9 eV for InN and bowing parameter of 2.63 eV to demonstrate that it does represent the Ga-rich side of the compositions well. However, the bowing parameter that is good for the entire compositional range is 1.43 eV, utilizing 0.77 eV for the band gap of InN.

There are isolated reports on electrical properties of the InGaN alloy. Nagatoma et al. [32.371] reported high-resistivity InGaN films with In compositions as high as 0.42. Background electron concentration as low as 10^{16} cm^{-3} has been reported for MOVPE-grown InGaN films. Conductivity control of both n-type and p-type InGaN was reported by Akasaki and Amano [32.374]. The growth and mobility of p-InGaN was also discussed by Yamasaki et al. [32.375]. Yoshimoto et al. [32.376] studied the effect of growth conditions on the carrier concentration and transport properties of $\text{In}_x\text{Ga}_{1-x}\text{N}$. They observed that increasing the deposition temperature of $\text{In}_x\text{Ga}_{1-x}\text{N}$ grown both on sapphire and ZnO with $x \approx 0.2$ results in a decrease in carrier concentration and increase in electron mobility. Nakamura and Mukai [32.150] discovered that the film quality of $\text{In}_x\text{Ga}_{1-x}\text{N}$ grown on high-quality GaN films could be significantly improved. Thus, it may be concluded that the major challenge for obtaining high-mobility InGaN is to find a compromise value for the growth temperature, since InN is unstable at typical GaN deposition temperatures. This growth temperature would undoubtedly be a function of the dopant atoms, as well as the method (MBE, OMVPE, etc.) used for the growth. This is evident from a study by Nakamura and coworkers, who have since expanded the study of InGaN employing Si [32.377] and Cd [32.378].

$\text{In}_{1-x}\text{Al}_x\text{N}$ is an important compound that can provide a lattice-matched barrier to GaN, low-fraction AlGaIn and InGaIn, and consequently, lattice-matched AlInN/AlGaIn or AlInN/InGaIn heterostructures would result. The growth and electrical properties of this semiconductor have not yet been extensively studied, as the growth of this ternary is also challenging because of the different thermal stability, lattice constant, and cohesive energy of AlN and InN. Kim et al. [32.379] deposited thin AlInN films and observed an increase of In content in AlInN of up to 8% by lowering the substrate temperature to 600 °C. Radio-frequency (RF) sputtering was employed to grow InAlN alloy by Starosta [32.380], and later Kubota et al. [32.342]. Kistenmacher et al. [32.381], on the other hand, used RF-magnetron sputtering (RF-MS) from a composite metal target to grow InAlN at 300 °C. It was observed that the energy band gap of this alloy varies between 2.0 eV and 6.20 eV for x between 0 and 1 [32.342]. Optical properties of 1- μm -thick $\text{Al}_{1-x}\text{In}_x\text{N}$ layers for x values up to the range of 0.19–0.44 have been investigated by absorption and photoluminescence [32.382]. Figure 32.37 shows results of the photoluminescence spectra from $\text{Al}_{1-x}\text{In}_x\text{N}$ layers. From the absorption spectra the band

Fig. 32.37 Band gap of $\text{In}_x\text{Al}_{1-x}\text{N}$ films for various In concentrations. Courtesy of Wlodek Walukiewicz

gaps are found to shift gradually with varying In content. Tailing of the band gap is also found to occur, probably due to fluctuation of the In content and grain boundaries. The PL peak-energy position shifts towards the lower-energy region with increasing In content as expected [32.383]. Considering that PL spectral line widths are much larger than expected from a completely random alloy, mechanisms other than alloy broadening such as microscopic phase separation might be invoked to account for such broadening. The small amount which the PL peak shifts (the same is true for the absorption edge) with mole fraction, x , might reflect the immiscibility of AlN in InN (or vice versa).

Transport data for InAlN are extremely scarce. The carrier concentration and the mobility of $\text{In}_{1-x}\text{Al}_x\text{N}$ for $x = 0.04$ were reported as $2 \times 10^{20} \text{ cm}^{-3}$ and $35 \text{ cm}^2/\text{Vs}$, respectively, and $8 \times 10^{19} \text{ cm}^{-3}$ and $2 \text{ cm}^2/\text{Vs}$ for $x = 0.25$, respectively [32.384]. The mobility was found to decrease substantially with an increase in the Al mole fraction and increase with an

increase in the In mole fraction, in close analogy with the parent compounds AlN and InN.

By alloying InN with GaN and AlN, the band gap of the resulting alloy(s) can be increased from 1.9 eV ($\approx 0.8 \text{ eV}$ if we use the recently determined InN band gap) to a value of 6.1 eV, which is critical for making high-efficiency visible-light sources and detectors. In addition, the band gap of this quaternary can be changed while keeping the lattice constant matched to GaN [32.385, 386]. In quaternary alloys of nitrides the N atoms constitute an anion sublattice while the three group III elements (In, Ga, Al) constitute the cation sublattice. Use of this quaternary material allows almost independent control of the band offset in AlInGaN-based heterostructures. However, among other difficulties brought about by the four-component system, the optimal growth temperature is important to optimize and control, as aluminium-based compounds generally require higher growth temperatures, while In-based compounds require lower temperatures. Higher temperatures are also desirable to reduce the incorporation of O into the growing film as oxides of Ga and In desorb from the surface. The growth temperature will therefore govern the limits of In and Al incorporation into the AlGaInN quaternary alloy [32.385]. Quaternary alloys, $(\text{Ga}_{1-x}\text{Al}_x)\text{In}_{1-y}\text{N}$, are expected to exist in the entire composition range $0 < x < 1$ and $0 < y < 1$. Unfortunately, as is the case for the InGaIn alloy, the incorporation of indium into these quaternary alloys is not easy. Ryu et al. [32.387] reported on optical emission in this quaternary system and AlInGaIn multiple quantum wells grown by pulsed metalorganic chemical-vapor deposition. A strong blue shift with excitation intensity was observed in both the quaternary layers and quantum wells, which was attributed to localization. This would imply that the structures are of inhomogeneous nature and/or presence of band-tail states indicative of early stages of material development and/or serious technological problems involved.

32.8 Summary and Conclusions

AlN exhibits many useful mechanical and electronic properties. For example, hardness, high thermal conductivity, resistance to high temperature and caustic chemicals combined with, in noncrystalline form, a reasonable thermal match to Si and GaAs, make AlN an attractive material for electronic packaging applications.

The wide band gap is also the reason for AlN to be touted as an insulating material in semiconductor device applications. Piezoelectric properties make AlN suitable for surface-acoustic-wave devices and sensor applications. However, the majority of interest in this semiconductor in the context of electronic and optoelectronic devices

stems from its ability to form alloys with GaN, producing AlGaIn and allowing the fabrication of electronic and optical devices based on AlGaIn/GaN and AlGaIn/InGaIn, the latter of which can be active from green wavelengths well into the ultraviolet. AlN also forms a crucial component of the nitride-based AlInGaIn quaternary which allows tuning of the band gap independently of the composition over a reasonably wide range of band gaps. This way, lattice-matched conditions to the underlying epitaxial structure can be maintained while being able to adjust the band gap.

AlN is not a particularly easy material to investigate because of the high reactivity of aluminium with oxygen in the growth vessel. Early measurements indicated that oxygen-contaminated material can lead to errors in the energy band gap and, depending on the extent of contamination, in the lattice constant. Only recently has the attainment of contamination-free deposition environments coupled with advanced procedures allowed researchers to grow higher-quality AlN consistently. Consequently, many of the physical properties of AlN have been reliably measured and bulk AlN synthesized.

Although GaN has been studied far more extensively than the other group III nitrides, there is still a great need for further investigations even to approach the level of understanding of technologically important materials such as Si and GaAs. GaN growth often suffers from relatively high background n-type carrier concentrations due to native defects and possibly impurities. The lack of commercially available native substrates exacerbates this situation. These, together with the difficulties in obtaining p-type doping, and the arcane fabrication processes, catalyzed the early bottlenecks, stymieing progress. Recent burgeoning interest has led to improvements in crystal-growth and processing technologies, and allowed many difficulties encountered earlier to be overcome. Consequently, a number of laboratories have begun to obtain high-quality GaN consistently with

room-temperature background electron concentrations as low as $5 \times 10^{16} \text{ cm}^{-3}$. The successful development of schemes leading to p-type GaN has led to the demonstration of excellent p-n-junction LEDs in the UV, violet, blue, green and even yellow bands of the visible spectrum with brightness suitable for outdoor displays, CW (continuous wave) lasers, power modulation doped field-effect transistors (MODFETs), and UV detectors, including those for the solar-blind region. Still, much work remains to be done in the determination of the fundamental physical properties of GaN.

InN has not received the experimental attention given to GaN and AlN. This is probably due to difficulties in growing high-quality crystalline InN samples, the poor luminescence properties of InN, and the existence of alternative, well-characterized/developed semiconductors such as AlGaAs and In (Ga, Al)AsP, which have energy band gaps close to what was thought to be the band gap of InN. More recent data and calculations appear to indicate that the band gap of InN is close to 0.7–0.8 eV. Even with this new band gap, InN does not escape competition in the sense that another well-developed semiconductor, InGaAs, covers that region. Consequently, practical applications of InN are restricted to its alloys with GaN and AlN, in addition to tandem solar cells. The growth of high-quality InN and the enumeration of its fundamental physical properties remain, for the present, a purely scientific enterprise. InN is not different from GaN and AlN in the sense that it suffers from the same lack of a suitable substrate material and, in particular, a high native-defect concentration. Moreover, early InN layers may have been polycrystalline and contained large concentrations of O and impurities and/or point defects resulting in large electron concentrations. The large band gap measured in early InN layers may have been caused by O, leading to oxides of In with large band gaps as well as a Burstein–Moss blue shift due to high electron concentrations.

33. Electron Transport Within the III–V Nitride Semiconductors, GaN, AlN, and InN: A Monte Carlo Analysis

The III–V nitride semiconductors, gallium nitride, aluminium nitride, and indium nitride, have been recognized as promising materials for novel electronic and optoelectronic device applications for some time now. Since informed device design requires a firm grasp of the material properties of the underlying electronic materials, the electron transport that occurs within these III–V nitride semiconductors has been the focus of considerable study over the years. In an effort to provide some perspective on this rapidly evolving field, in this paper we review analyses of the electron transport within these III–V nitride semiconductors. In particular, we discuss the evolution of the field, compare and contrast results obtained by different researchers, and survey the current literature. In order to narrow the scope of this chapter, we will primarily focus on electron transport within bulk wurtzite gallium nitride, aluminium nitride, and indium nitride for this analysis. Most of our discussion will focus on results obtained from our ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within these materials, our results conforming with state-of-the-art III–V nitride semiconductor orthodoxy. Steady-state and transient electron transport results are presented. We conclude our discussion by presenting some recent developments on the electron transport within these materials.

33.1 Electron Transport Within Semiconductors and the Monte Carlo Simulation Approach	806
33.1.1 The Boltzmann Transport Equation	807
33.1.2 Our Ensemble Semi-Classical Monte Carlo Simulation Approach	808
33.1.3 Parameter Selections for Bulk Wurtzite GaN, AlN, and InN	808
33.2 Steady-State and Transient Electron Transport Within Bulk Wurtzite GaN, AlN, and InN	810
33.2.1 Steady-State Electron Transport Within Bulk Wurtzite GaN	811
33.2.2 Steady-State Electron Transport: A Comparison of the III–V Nitride Semiconductors with GaAs	812
33.2.3 Influence of Temperature on the Electron Drift Velocities Within GaN and GaAs	812
33.2.4 Influence of Doping on the Electron Drift Velocities Within GaN and GaAs	815
33.2.5 Electron Transport in AlN	816
33.2.6 Electron Transport in InN	818
33.2.7 Transient Electron Transport	820
33.2.8 Electron Transport: Conclusions	822
33.3 Electron Transport Within III–V Nitride Semiconductors: A Review	822
33.3.1 Evolution of the Field	822
33.3.2 Recent Developments	824
33.3.3 Future Perspectives	825
33.4 Conclusions	826
References	826

The III–V nitride semiconductors, gallium nitride (GaN), aluminium nitride (AlN), and indium nitride (InN), have been known as promising materials for novel electronic and optoelectronic device applications for some time now [33.1–4]. In terms of electronics, their wide energy gaps, large breakdown fields, high thermal conductivities, and favorable electron transport characteristics, make GaN, AlN, and InN, and alloys of these materials, ideally suited for novel

high-power and high-frequency electron device applications. On the optoelectronics front, the direct nature of the energy gaps associated with GaN, AlN, and InN, make this family of materials, and its alloys, well suited for novel optoelectronic device applications in the visible and ultraviolet frequency range. While initial efforts to study these materials were hindered by growth difficulties, recent improvements in material quality have made the realization of a number of

III–V nitride semiconductor-based electronic [33.5–9] and optoelectronic [33.9–12] devices possible. These developments have fueled considerable interest in these III–V nitride semiconductors.

In order to analyze and improve the design of III–V nitride semiconductor-based devices, an understanding of the electron transport that occurs within these materials is necessary. Electron transport within bulk GaN, AlN, and InN has been examined extensively over the years [33.13–32]. Unfortunately, uncertainty in the material parameters associated with GaN, AlN, and InN remains a key source of ambiguity in the analysis of the electron transport within these materials [33.32]. In addition, some recent experimental [33.33] and theoretical [33.34] developments have cast doubt upon the validity of widely accepted notions upon which our understanding of the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN, has evolved. Another confounding matter is the sheer volume of research activity being performed on the electron transport within these materials, presenting the researcher with a dizzying array of seemingly disparate approaches and results. Clearly, at this critical juncture at least, our understanding of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, remains in a state of flux.

In order to provide some perspective on this rapidly evolving field, we aim to review analyses of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, within this paper. In particular, we will discuss the evolution of the field and survey the current literature. In order to narrow the scope of this review, we will primarily focus on the electron transport within bulk wurtzite GaN, AlN, and InN for the purposes of this paper. Most of our discussion will focus upon results obtained from our ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within

these materials, our results conforming with state-of-the-art III–V nitride semiconductor orthodoxy. We hope that researchers in the field will find this review useful and informative.

We begin our review with the Boltzmann transport equation, which underlies most analyses of the electron transport within semiconductors. The ensemble semi-classical three-valley Monte Carlo simulation approach that we employ in order to solve this Boltzmann transport equation is then discussed. The material parameters corresponding to bulk wurtzite GaN, AlN, and InN are then presented. We then use these material parameter selections and our ensemble semi-classical three-valley Monte Carlo simulation approach to determine the nature of the steady-state and transient electron transport within the III–V nitride semiconductors. Finally, we present some recent developments on the electron transport within these materials.

This paper is organized in the following manner. In Sect. 33.1, we present the Boltzmann transport equation and our ensemble semi-classical three-valley Monte Carlo simulation approach that we employ in order to solve this equation for the III–V nitride semiconductors, GaN, AlN, and InN. The material parameters, corresponding to bulk wurtzite GaN, AlN, and InN, are also presented in Sect. 33.1. Then, in Sect. 33.2, using results obtained from our ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within these III–V nitride semiconductors, we study the nature of the steady-state electron transport that occurs within these materials. Transient electron transport within the III–V nitride semiconductors is also discussed in Sect. 33.2. A review of the III–V nitride semiconductor electron transport literature, in which the evolution of the field is discussed and a survey of the current literature is presented, is then featured in Sect. 33.3. Finally, conclusions are provided in Sect. 33.4.

33.1 Electron Transport Within Semiconductors and the Monte Carlo Simulation Approach

The electrons within a semiconductor are in a perpetual state of motion. In the absence of an applied electric field, this motion arises as a result of the thermal energy that is present, and is referred to as thermal motion. From the perspective of an individual electron, thermal motion may be viewed as a series of trajectories, interrupted by a series of random scattering events. Scattering may arise

as a result of interactions with the lattice atoms, impurities, other electrons, and defects. As these interactions lead to electron trajectories in all possible directions, i.e., there is no preferred direction, while individual electrons will move from one location to another, when taken as an ensemble, and assuming that the electrons are in thermal equilibrium, the overall electron distribu-

tion will remain static. Accordingly, no net current flow occurs.

With the application of an applied electric field, E , each electron in the ensemble will experience a force, $-qE$. While this force may have a negligible impact upon the motion of any given individual electron, taken as an ensemble, the application of such a force will lead to a net aggregate motion of the electron distribution. Accordingly, a net current flow will occur, and the overall electron ensemble will no longer be in thermal equilibrium. This movement of the electron ensemble in response to an applied electric field, in essence, represents the fundamental issue at stake when we study the electron transport within a semiconductor.

In this section, we provide a brief tutorial on the issues at stake in our analysis of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN. We begin our analysis with an introduction to the Boltzmann transport equation. This equation describes how the electron distribution function evolves under the action of an applied electric field, and underlies the electron transport within bulk semiconductors. We then introduce the Monte Carlo simulation approach to solving this Boltzmann transport equation, focusing on the ensemble semi-classical three-valley Monte Carlo simulation approach used in our simulations of the electron transport within the III–V nitride semiconductors. Finally, we present the material parameters corresponding to bulk wurtzite GaN, AlN, and InN.

This section is organized in the following manner. In Sect. 33.1.1, the Boltzmann transport equation is introduced. Then, in Sect. 33.1.2, our ensemble semi-classical three-valley Monte Carlo simulation approach to solving this Boltzmann transport equation is presented. Finally, in Sect. 33.1.3, our material parameter selections, corresponding to bulk wurtzite GaN, AlN, and InN, are presented.

33.1.1 The Boltzmann Transport Equation

An electron ensemble may be characterized by its distribution function, $f(\mathbf{r}, \mathbf{p}, t)$, where \mathbf{r} denotes the position, \mathbf{p} represents the momentum, and t indicates time. The response of this distribution function to an applied electric field, E , is the issue at stake when one investigates the electron transport within a semiconductor. When the dimensions of the semiconductor are large, and quantum effects are negligible, the ensemble of electrons may be treated as a continuum, so the corpuscular nature of the individual electrons within the ensemble, and the attendant complications which

arise, may be neglected. In such a circumstance, the evolution of the distribution function, $f(\mathbf{r}, \mathbf{p}, t)$, may be determined using the Boltzmann transport equation. In contrast, when the dimensions of the semiconductor are small, and quantum effects are significant, then the Boltzmann transport equation, and its continuum description of the electron ensemble, is no longer valid. In such a case, it is necessary to adopt quantum transport methods in order to study the electron transport within the semiconductor [33.35].

For the purposes of this analysis, we will focus on the electron transport within bulk semiconductors, i.e., semiconductors of sufficient dimensions so that the Boltzmann transport equation is valid. *Ashcroft* and *Mermin* [33.36] demonstrated that this equation may be expressed as

$$\frac{\partial f}{\partial t} = -\dot{\mathbf{p}} \cdot \nabla_{\mathbf{p}} f - \dot{\mathbf{r}} \cdot \nabla_{\mathbf{r}} f + \left. \frac{\partial f}{\partial t} \right|_{\text{scat}}. \quad (33.1)$$

The first term on the right-hand side of (33.1) represents the change in the distribution function due to external forces applied to the system. The second term on the right-hand side of (33.1) accounts for the electron diffusion which occurs. The final term on the right-hand side of (33.1) describes the effects of scattering.

Owing to its fundamental importance in the analysis of the electron transport within semiconductors, a number of techniques have been developed over the years in order to solve the Boltzmann transport equation. Approximate solutions to the Boltzmann transport equation, such as the displaced Maxwellian distribution function approach of *Ferry* [33.14] and *Das* and *Ferry* [33.15] and the nonstationary charge transport analysis of *Sandborn* et al. [33.37], have proven useful. Low-field approximate solutions have also proven elementary and insightful [33.17, 20, 38]. A number of these techniques have been applied to the analysis of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN [33.14, 15, 17, 20, 38, 39]. Alternatively, more sophisticated techniques have been developed which solve the Boltzmann transport equation directly. These techniques, while allowing for a rigorous solution of the Boltzmann transport equation, are rather involved, and require intense numerical analysis. They are further discussed by *Nag* [33.40].

For studies of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, by far the most common approach to solving the Boltzmann transport equation has been the ensemble semi-classical Monte Carlo simulation approach. Of the III–V nitride semiconductors, the electron transport within GaN

has been studied the most extensively using this ensemble Monte Carlo simulation approach [33.13, 16, 18, 19, 21, 22, 27, 29, 32], with AlN [33.24, 25, 29] and InN [33.23, 28, 29, 31] less so. The Monte Carlo simulation approach has also been used to study the electron transport within the two-dimensional electron gas of the AlGaIn/GaN interface which occurs in high electron mobility AlGaIn/GaN field-effect transistors [33.41, 42].

At this point, it should be noted that the complete solution of the Boltzmann transport equation requires the resolution of both steady-state and transient responses. Steady-state electron transport refers to the electron transport that occurs long after the application of an applied electric field, i. e., once the electron ensemble has settled to a new equilibrium state (we are not necessarily referring to thermal equilibrium here, since thermal equilibrium is only achieved in the absence of an applied electric field). As the distribution function is difficult to visualize quantitatively, researchers typically study the dependence of the electron drift velocity (the average electron velocity determined by statistically averaging over the entire electron ensemble) on the applied electric field in the analysis of steady-state electron transport; in other words, they determine the velocity–field characteristic. Transient electron transport, by way of contrast, refers to the transport that occurs while the electron ensemble is evolving into its new equilibrium state. Typically, it is characterized by studying the dependence of the electron drift velocity on the time elapsed, or the distance displaced, since the electric field was initially applied. Both steady-state and transient electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, are reviewed within this paper.

33.1.2 Our Ensemble Semi-Classical Monte Carlo Simulation Approach

For the purposes of our analysis of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, we employ ensemble semi-classical Monte Carlo simulations. A three-valley model for the conduction band is employed. Nonparabolicity is considered in the lowest conduction band valley, this nonparabolicity being treated through the application of the Kane model [33.43].

In the Kane model, the energy band of the Γ valley is assumed to be nonparabolic, spherical, and of the form

$$\frac{\hbar^2 k^2}{2m^*} = E(1 + \alpha E), \quad (33.2)$$

where $\hbar k$ denotes the crystal momentum, E represents the energy above the minimum, m^* is the effective mass, and the nonparabolicity coefficient, α , is given by

$$\alpha = \frac{1}{E_g} \left(1 - \frac{m^*}{m_e}\right)^2, \quad (33.3)$$

where m_e and E_g denote the free electron mass and the energy gap, respectively [33.43].

The scattering mechanisms considered in our analysis are (1) ionized impurity, (2) polar optical phonon, (3) piezoelectric [33.44, 45], and (4) acoustic deformation potential. Intervalley scattering is also considered. Piezoelectric scattering is treated using the well established zinc blende scattering rates, and so a suitably transformed piezoelectric constant, e_{14} , must be selected. This may be achieved through the transformation suggested by Bykhovski et al. [33.44, 45]. We also assume that all donors are ionized and that the free electron concentration is equal to the dopant concentration. The motion of three thousand electrons is examined in our steady-state electron transport simulations, while the motion of ten thousand electrons is considered in our transient electron transport simulations. The crystal temperature is set to 300 K and the doping concentration is set to 10^{17} cm^{-3} in all cases, unless otherwise specified. Electron degeneracy effects are accounted for by means of the rejection technique of Lugli and Ferry [33.46]. Electron screening is also accounted for following the Brooks–Herring method [33.47]. Further details of our approach are discussed in the literature [33.16, 21–24, 29, 32, 48].

33.1.3 Parameter Selections for Bulk Wurtzite GaN, AlN, and InN

The material parameter selections, used for our simulations of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, are tabulated in Table 33.1. These parameter selections are the same as those employed by Foutz et al. [33.29]. While the band structures corresponding to bulk wurtzite GaN, AlN, and InN are still not agreed upon, the band structures of Lambrecht and Segall [33.49] are adopted for the purposes of this analysis. For the case of bulk wurtzite GaN, the analysis of Lambrecht and Segall [33.49] suggests that the lowest point in the conduction band is located at the center of the Brillouin zone, at the Γ point, the first upper conduction band valley minimum also occurring at the Γ point, 1.9 eV above the lowest point in the conduction band, the second upper conduction

Table 33.1 The material parameter selections corresponding to bulk wurtzite GaN, AlN, and InN. These parameter selections are from Foutz et al. [33.29]

Parameter	GaN	AlN	InN
Mass density (g/cm ³)	6.15	3.23	6.81
Longitudinal sound velocity (cm/s)	6.56×10^5	9.06×10^5	6.24×10^5
Transverse sound velocity (cm/s)	2.68×10^5	3.70×10^5	2.55×10^5
Acoustic deformation potential (eV)	8.3	9.5	7.1
Static dielectric constant	8.9	8.5	15.3
High-frequency dielectric constant	5.35	4.77	8.4
Effective mass (Γ_1 valley)	$0.20 m_e$	$0.48 m_e$	$0.11 m_e$
Piezoelectric constant, e_{14} (C/cm ²)	3.75×10^{-5}	9.2×10^{-5}	3.75×10^{-5}
Direct energy gap (eV)	3.39	6.2	1.89
Optical phonon energy (meV)	91.2	99.2	89.0
Intervalley deformation potentials (eV/cm)	10^9	10^9	10^9
Intervalley phonon energies (meV)	91.2	99.2	89.0

Table 33.2 The valley parameter selections corresponding to bulk wurtzite GaN, AlN, and InN. These parameter selections are from Foutz et al. [33.29]. These parameters were originally determined from the band structural calculations of Lambrecht and Segall [33.49]

	Valley number	1	2	3
GaN	Valley location	Γ_1	Γ_2	L–M
	Valley degeneracy	1	1	6
	Effective mass	$0.2 m_e$	m_e	m_e
	Intervalley energy separation (eV)	—	1.9	2.1
	Energy gap (eV)	3.39	5.29	5.49
	Nonparabolicity (eV ^{−1})	0.189	0.0	0.0
AlN	Valley location	Γ_1	L–M	K
	Valley degeneracy	1	6	2
	Effective mass	$0.48 m_e$	m_e	m_e
	Intervalley energy separation (eV)	—	0.7	1.0
	Energy gap (eV)	6.2	6.9	7.2
	Nonparabolicity (eV ^{−1})	0.044	0.0	0.0
InN	Valley location	Γ_1	A	Γ_2
	Valley degeneracy	1	1	1
	Effective mass	$0.11 m_e$	m_e	m_e
	Intervalley energy separation (eV)	—	2.2	2.6
	Energy gap (eV)	1.89	4.09	4.49
	Nonparabolicity (eV ^{−1})	0.419	0.0	0.0

band valley minima occurring along the symmetry lines between the L and M points, 2.1 eV above the lowest point in the conduction band; see Table 33.2. For the case of bulk wurtzite AlN, the analysis of Lambrecht and Segall [33.49] suggests that the lowest point in the conduction band is located at the center of the Brillouin zone, at the Γ point, the first upper conduction band valley minima occurring along the symmetry lines between the L and M points, 0.7 eV above the lowest

point in the conduction band, the second upper conduction band valley minima occurring at the K points, 1 eV above the lowest point in the conduction band; see Table 33.2. For the case of bulk wurtzite InN, the analysis of Lambrecht and Segall [33.49] suggests that the lowest point in the conduction band is located at the center of the Brillouin zone, at the Γ point, the first upper conduction band valley minimum occurring at the A point, 2.2 eV above the lowest point in the conduction band,

the second upper conduction band valley minimum occurring at the Γ point, 2.6 eV above the lowest point in the conduction band; see Table 33.2. We ascribe an effective mass equal to the free electron mass, m_e , to all of the upper conduction band valleys. The nonparabolicity coefficient, α , corresponding to each upper conduction band valley is set to zero, so the upper conduction band valleys are assumed to be completely parabolic. For our simulations of the electron transport within gallium arsenide (GaAs), the material parameters employed are mostly from *Littlejohn* et al. [33.50], although it should be noted that the mass density, the energy gap, and the sound velocities are from *Blakemore* [33.51].

It should be noted that the energy gap associated with InN has been the subject of some controversy since 2002. The pioneering experimental results of *Tansley* and *Foley* [33.52], reported in 1986, suggested that InN has an energy gap of 1.89 eV. This value has been used extensively in Monte Carlo simulations of the electron transport within this material since that time [33.23, 28, 29, 31]; typically, the influence of the energy gap on the electron transport occurs through its impact on the nonparabolicity coefficient, α . In 2002, *Davydov* et al. [33.53], *Wu* et al. [33.54], and *Matsuoka* et al. [33.55], presented experimental evidence which instead suggests a considerably smaller energy gap for InN, around 0.7 eV. As this new result is still the subject of some controversy, we adopt the traditional *Tansley* and *Foley* [33.52] energy gap value for the purposes of

our present analysis, noting that even if the newer value for the energy gap was adopted, it would only change our electron transport results marginally; the sensitivity of the velocity–field characteristic associated with bulk wurtzite GaN to variations in the nonparabolicity coefficient, α , has been explored, in detail, by *O’Leary* et al. [33.32].

The band structure associated with bulk wurtzite GaN has also been the focus of some controversy. In particular, *Brazel* et al. [33.56] employed ballistic electron emission microscopy measurements in order to demonstrate that the first upper conduction band valley occurs only 340 meV above the lowest point in the conduction band for this material. This contrasts rather dramatically with more traditional results, such as the calculation of *Lambrecht* and *Segall* [33.49], which instead suggest that the first upper conduction band valley minimum within wurtzite GaN occurs about 2 eV above the lowest point in the conduction band. Clearly, this will have a significant impact upon the results. While the results of *Brazel* et al. [33.56] were reported in 1997, electron transport simulations adopted the more traditional intervalley energy separation of about 2 eV until relatively recently. Accordingly, we have adopted the more traditional intervalley energy separation for the purposes of our present analysis. The sensitivity of the velocity–field characteristic associated with bulk wurtzite GaN to variations in the intervalley energy separation has been explored, in detail, by *O’Leary* et al. [33.32].

33.2 Steady-State and Transient Electron Transport Within Bulk Wurtzite GaN, AlN, and InN

The current interest in the III–V nitride semiconductors, GaN, AlN, and InN, is primarily being fueled by the tremendous potential of these materials for novel electronic and optoelectronic device applications. With the recognition that informed electronic and optoelectronic device design requires a firm understanding of the nature of the electron transport within these materials, electron transport within the III–V nitride semiconductors has been the focus of intensive investigation over the years. The literature abounds with studies on steady-state and transient electron transport within these materials [33.13–34, 38, 39, 41, 42, 48]. As a result of this intense flurry of research activity, novel III–V nitride semiconductor-based devices are starting to be deployed in today’s commercial products. Future developments in the III–V nitride semiconductor field will undoubtedly require an even deeper understand-

ing of the electron transport mechanisms within these materials.

In the previous section, we presented details of the Monte Carlo simulation approach that we employ for the analysis of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN. In this section, an overview of the steady-state and transient electron transport results we obtained from these Monte Carlo simulations is provided. In the first part of this section, we focus upon bulk wurtzite GaN. In particular, the velocity–field characteristic associated with this material will be examined in detail. Then, an overview of our steady-state electron transport results, corresponding to the three III–V nitride semiconductors under consideration in this analysis, will be given, and a comparison with the more conventional III–V compound semiconductor, GaAs, will be presented. A comparison between the tem-

perature dependence of the velocity–field characteristics associated with GaN and GaAs will then be presented, and our Monte Carlo results will be used to account for the differences in behavior. A similar analysis will be presented for the doping dependence. Next, detailed simulation results for AlN and InN will be presented. Finally, the transient electron transport that occurs within the III–V nitride semiconductors, GaN, AlN, and InN, is determined and compared with that in GaAs.

This section is organized in the following manner. In Sect. 33.2.1, the velocity–field characteristic associated with bulk wurtzite GaN is presented and analyzed. Then, in Sect. 33.2.2, the velocity–field characteristics associated with the III–V nitride semiconductors under consideration in this analysis will be compared and contrasted with that of GaAs. The sensitivity of the velocity–field characteristic associated with bulk wurtzite GaN to variations in the crystal temperature will then be examined in Sect. 33.2.3, and a comparison with that corresponding to GaAs presented. In Sect. 33.2.4, the sensitivity of the velocity–field characteristic associated with bulk wurtzite GaN to variations in the doping concentration level will be explored, and a comparison with that corresponding to GaAs presented. The velocity–field characteristics associated with AlN and InN will then be examined in Sect. 33.2.5 and Sect. 33.2.6, respectively. Our transient electron transport analysis results are then presented in Sect. 33.2.7. Finally, the conclusions of this electron transport analysis are summarized in Sect. 33.2.8.

33.2.1 Steady-State Electron Transport Within Bulk Wurtzite GaN

Our examination of results begins with GaN, the most commonly studied III–V nitride semiconductor. The velocity–field characteristic associated with this material is presented in Fig. 33.1. This result was obtained through our Monte Carlo simulations of the electron transport within this material for the bulk wurtzite GaN parameter selections specified in Table 33.1 and Table 33.2; the crystal temperature was set to 300 K and the doping concentration to 10^{17} cm^{-3} . We see that for applied electric fields in excess of 140 kV/cm, the electron drift velocity decreases, eventually saturating at $1.4 \times 10^7 \text{ cm/s}$ for high applied electric fields. By examining the results of our Monte Carlo simulation further, an understanding of this result becomes clear.

First, we discuss the results at low applied electric fields, i. e., applied electric fields of less than 30 kV/cm. This is referred to as the linear regime of electron trans-

Fig. 33.1 The velocity–field characteristic associated with bulk wurtzite GaN. Like many other compound semiconductors, the electron drift velocity reaches a peak, and at higher applied electric fields it decreases until it saturates

port as the electron drift velocity is well characterized by the low-field electron drift mobility, μ , in this regime, i. e., a linear low-field electron drift velocity dependence on the applied electric field $v_d = \mu E$, applies in this regime. Examining the distribution function for this regime, we find that it is very similar to the zero-field distribution function with a slight shift in the direction opposite to the applied electric field. In this regime, the average electron energy remains relatively low, with most of the energy gained from the applied electric field being transferred into the lattice through polar optical phonon scattering.

If we examine the average electron energy as a function of the applied electric field, shown in Fig. 33.2, we see that there is a sudden increase at around 100 kV/cm. In order to understand why this increase occurs, we note that the dominant energy loss mechanism for many of the III–V compound semiconductors, including GaN, is polar optical phonon scattering. When the applied electric field is less than 100 kV/cm, all of the energy that the electrons gain from the applied electric field is lost through polar optical phonon scattering. The other scattering mechanisms, i. e., ionized impurity scattering, piezoelectric scattering and acoustic deformation potential scattering, do not remove energy from the electron ensemble: they are elastic scattering mechanisms. However, beyond a certain critical applied electric field strength, the polar optical phonon scattering mechanism can no longer remove all of the energy gained from the applied electric field. Other scattering mechanisms must start to play a role if the electron ensemble is to remain in equilibrium. The average electron energy increases

until intervalley scattering begins and an energy balance is re-established.

Fig. 33.2 The average electron energy as a function of the applied electric field for bulk wurtzite GaN. Initially, the average electron energy remains low, only slightly higher than the thermal energy, $\frac{3}{2}k_B T$. At 100 kV/cm, however, the average electron energy increases dramatically. This increase is due to the fact that the polar optical phonon scattering mechanism can no longer absorb all of the energy gained from the applied electric field

Fig. 33.3 The valley occupancy as a function of the applied electric field for the case of bulk wurtzite GaN. Soon after the average electron energy increases, electrons begin to transfer to the upper valleys of the conduction band. Three thousand electrons were employed for this simulation. The valleys are labeled 1, 2, and 3, in accordance with their energy minima; the lowest energy valley is valley 1, the next higher energy valley is valley 2, and the highest energy valley is valley 3

As the applied electric field is increased beyond 100 kV/cm, the average electron energy increases until a substantial fraction of the electrons have acquired enough energy in order to transfer into the upper valleys. As the effective mass of the electrons in the upper valleys is greater than that in the lowest valley, the electrons in the upper valleys will be slower. As more electrons transfer to the upper valleys (Fig. 33.3), the electron drift velocity decreases. This accounts for the negative differential mobility observed in the velocity–field characteristic depicted in Fig. 33.1.

Finally, at high applied electric fields, the number of electrons in each valley saturates. It can be shown that in the high-field limit the number of electrons in each valley is proportional to the product of the density of states of that particular valley and the corresponding valley degeneracy. At this point, the electron drift velocity stops decreasing and achieves saturation.

Thus far, electron transport results corresponding to bulk wurtzite GaN have been presented and discussed qualitatively. It should be noted, however, that the same phenomenon that occurs in the velocity–field characteristic associated with GaN also occurs for the other III–V nitride semiconductors, AlN and InN. The importance of polar optical phonon scattering when determining the nature of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, will become even more apparent later, as it will be used to account for much of the electron transport behavior within these materials.

33.2.2 Steady-State Electron Transport: A Comparison of the III–V Nitride Semiconductors with GaAs

Setting the crystal temperature to 300 K and the level of doping to 10^{17} cm^{-3} , the velocity–field characteristics associated with the III–V nitride semiconductors under consideration in this analysis – GaN, AlN, and InN – are contrasted with that of GaAs in Fig. 33.4. We see that each of these III–V compound semiconductors achieves a peak in its velocity–field characteristic. InN achieves the highest steady-state peak electron drift velocity, $4.1 \times 10^7 \text{ cm/s}$ at an applied electric field of 65 kV/cm. This contrasts with the case of GaN, $2.9 \times 10^7 \text{ cm/s}$ at 140 kV/cm, and that of AlN, $1.7 \times 10^7 \text{ cm/s}$ at 450 kV/cm. For GaAs, the peak electron drift velocity of $1.6 \times 10^7 \text{ cm/s}$ occurs at a much lower applied electric field than that for the III–V nitride semiconductors (only 4 kV/cm).

Fig. 33.4 A comparison of the velocity–field characteristics associated with the III–V nitride semiconductors, GaN, AlN, and InN, with that associated with GaAs. After [33.29] with permission, copyright AIP

33.2.3 Influence of Temperature on the Electron Drift Velocities Within GaN and GaAs

The temperature dependence of the velocity–field characteristic associated with bulk wurtzite GaN is now examined. Figure 33.5a shows how the velocity–field characteristic associated with bulk wurtzite GaN varies as the crystal temperature is increased from 100 to 700 K, in increments of 200 K. The upper limit, 700 K, is chosen as it is the highest operating temperature that

may be expected for AlGaN/GaN power devices. To highlight the difference between the III–V nitride semiconductors with more conventional III–V compound semiconductors, such as GaAs, Monte Carlo simulations of the electron transport within GaAs have also been performed under the same conditions as GaN. Figure 33.5b shows the results of these simulations. Note that the electron drift velocity for the case of GaN is much less sensitive to changes in temperature than that associated with GaAs.

To quantify this dependence further, the low-field electron drift mobility, the peak electron drift velocity, and the saturation electron drift velocity are plotted as a function of the crystal temperature in Fig. 33.6, these results being determined from our Monte Carlo simulations of the electron transport within these materials. For both GaN and GaAs, it is found that all of these electron transport metrics diminish as the crystal temperature is increased. As may be seen through an inspection of Fig. 33.5, the peak and saturation electron drift velocities do not drop as much in GaN as they do in GaAs in response to increases in the crystal temperature. The low-field electron drift mobility in GaN, however, is seen to fall quite rapidly with temperature, this drop being particularly severe for temperatures at and below room temperature. This property will likely have an impact on high-power device performance.

Delving deeper into our Monte Carlo results yields clues to the reason for this variation in temperature dependence. First, we examine the polar optical phonon scattering rate as a function of the applied electric field strength. Figure 33.7 shows that the scattering rate only

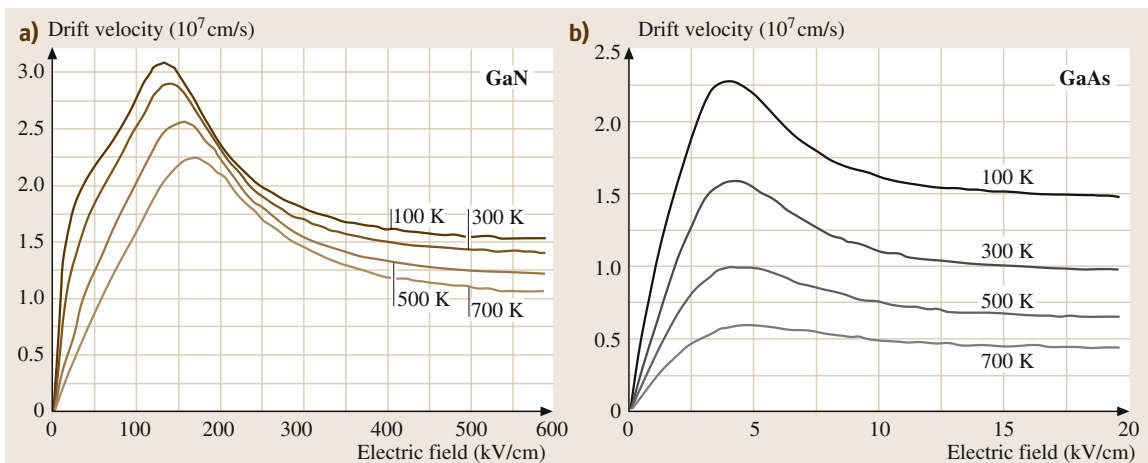

Fig. 33.5a,b A comparison of the temperature dependence of the velocity–field characteristics associated with (a) GaN and (b) GaAs. GaN maintains a higher electron drift velocity with increased temperatures than GaAs does

Fig. 33.6a,b A comparison of the temperature dependence of the low-field electron drift mobility (*solid lines*), the peak electron drift velocity (*diamonds*), and the saturation electron drift velocity (*solid points*) for (a) GaN and (b) GaAs. The low-field electron drift mobility of GaN drops quickly with increasing temperature, but its peak and saturation electron drift velocities are less sensitive to increases in temperature than GaAs

Fig. 33.7a,b A comparison of the polar optical phonon scattering rates as a function of the applied electric field strength for various crystal temperatures for (a) GaN and (b) GaAs. Polar optical phonon scattering is seen to increase much more quickly with temperature in GaAs

increases slightly with temperature for the case of GaN, from $6.7 \times 10^{13} \text{ s}^{-1}$ at 100 K to $8.6 \times 10^{13} \text{ s}^{-1}$ at 700 K, for high applied electric field strengths. Contrast this with the case of GaAs, where the rate increases from $4.0 \times 10^{12} \text{ s}^{-1}$ at 100 K to more than twice that amount at 700 K, $9.2 \times 10^{12} \text{ s}^{-1}$, at high applied electric field strengths. This large increase in the polar optical phonon scattering rate for the case of GaAs is one reason for the large drop in the electron drift velocity with increasing temperature for the case of GaAs.

A second reason for the variation in temperature dependence of the two materials is the occupancy of the upper valleys, shown in Fig. 33.8. In the case of GaN, the upper valleys begin to become occupied at roughly the same applied electric field strength, 100 kV/cm, independent of temperature. For the case of GaAs, however, the upper valleys are at a much lower energy than those in GaN. In particular, while the first upper conduction band valley minimum is 1.9 eV above the lowest point in the conduction band in GaN, the first upper conduc-

Fig. 33.8a,b A comparison of the number of particles in the lowest energy valley of the conduction band, the Γ valley, as a function of the applied electric field for various crystal temperatures, for the cases of (a) GaN and (b) GaAs. In GaAs, the electrons begin to occupy the upper valleys much more quickly, causing the electron drift velocity to drop as the crystal temperature is increased. Three thousand electrons were employed for these steady-state electron transport simulations

tion band valley is only 290 meV above the bottom of the conduction band in GaAs [33.51]. As the upper conduction band valleys are so close to the bottom of the conduction band for the case of GaAs, the thermal energy (at 700 K, $k_B T \simeq 60$ meV) is enough in order to allow for a small fraction of the electrons to transfer into the upper valleys even before an electric field is applied. When electrons occupy the upper valleys, intervalley scattering and the upper valleys' larger effective masses reduce the overall electron drift velocity. This

is another reason why the velocity–field characteristic associated with GaAs is more sensitive to variations in crystal temperature than that associated with GaN.

33.2.4 Influence of Doping on the Electron Drift Velocities Within GaN and GaAs

One parameter that can be readily controlled during the fabrication of semiconductor devices is the doping concentration. Understanding the effect of doping

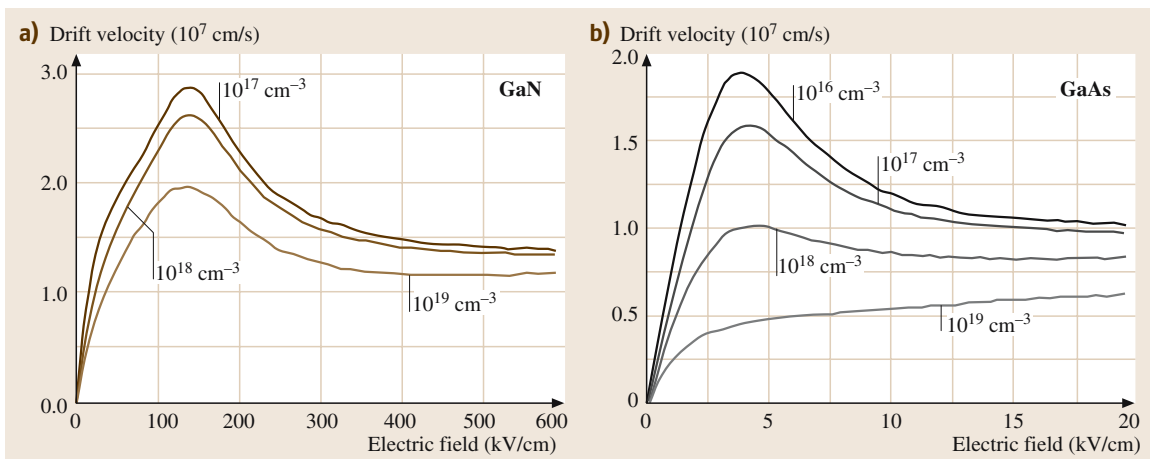

Fig. 33.9a,b A comparison of the dependence of the velocity–field characteristics associated with (a) GaN and (b) GaAs on the doping concentration. GaN maintains a higher electron drift velocity with increased doping levels than GaAs does

Fig. 33.10a,b A comparison of the low-field electron drift mobility (*solid lines*), the peak electron drift velocity (*diamonds*), and the saturation electron drift velocity (*solid points*) for **(a)** GaN and **(b)** GaAs as a function of the doping concentration. These parameters are more insensitive to increases in doping in GaN than in GaAs

on the resultant electron transport is also important. In Fig. 33.9, the velocity–field characteristic associated with GaN is presented for a number of different doping concentration levels. Once again, three important electron transport metrics are influenced by the doping concentration level: the low-field electron drift mobility, the peak electron drift velocity, and the saturation electron drift velocity; see Fig. 33.10. Our simulation results suggest that for doping concentrations of less than 10¹⁷ cm⁻³, there is very little effect on the velocity–field characteristic for the case of GaN. However, for doping concentrations above 10¹⁷ cm⁻³, the peak electron drift velocity diminishes considerably, from 2.9 × 10⁷ cm/s for the case of 10¹⁷ cm⁻³ doping to 2.0 × 10⁷ cm/s for the case of 10¹⁹ cm⁻³ doping. The saturation electron drift velocity within GaN is found to only decrease slightly in response to increases in the doping concentration. The effect of doping on the low-field electron drift mobility is also shown. It is seen that this mobility drops significantly in response to increases in the doping concentration level, from 1200 cm²/Vs at 10¹⁶ cm⁻³ doping to 400 cm²/Vs at 10¹⁹ cm⁻³ doping.

As we did for temperature, we compare the sensitivity of the velocity–field characteristic associated with GaN to doping with that associated with GaAs. Figure 33.9 shows this comparison. For the case of GaAs, it is seen that the electron drift velocities decrease much more with increased doping than those associated with GaN. In particular, for the case of GaAs, the peak electron drift velocity decreases from 1.8 × 10⁷ cm/s at 10¹⁶ cm⁻³ doping to 0.6 × 10⁷ cm/s at 10¹⁹ cm⁻³ dop-

ing. For GaAs, at the higher doping levels, the peak in the velocity–field characteristic disappears completely for sufficiently high doping concentrations. The saturation electron drift velocity decreases from 1.0 × 10⁷ cm/s at 10¹⁶ cm⁻³ doping to 0.6 × 10⁷ cm/s at 10¹⁹ cm⁻³ doping. The low-field electron drift mobility also diminishes dramatically with increased doping, dropping from 7800 cm²/Vs at 10¹⁶ cm⁻³ doping to 2200 cm²/Vs at 10¹⁹ cm⁻³ doping.

Once again, it is interesting to determine why the doping dependence in GaAs is so much more pronounced than it is in GaN. Again, we examine the polar optical phonon scattering rate and the occupancy of the upper valleys. Figure 33.11 shows the polar optical phonon scattering rates as a function of the applied electric field, for both GaN and GaAs. In this case, however, due to screening effects, the rate drops when the doping concentration is increased. The decrease, however, is much more pronounced for the case of GaAs than for GaN. It is believed that this drop in the polar optical phonon scattering rate allows for upper valley occupancy to occur more quickly in GaAs rather than in GaN (Fig. 33.12). For GaN, electrons begin to occupy the upper valleys at roughly the same applied electric field strength, independent of the doping level. However, for the case of GaAs, the upper valleys are occupied more quickly with greater doping. When the upper valleys are occupied, the electron drift velocity decreases due to intervalley scattering and the larger effective mass of the electrons within the upper valleys.

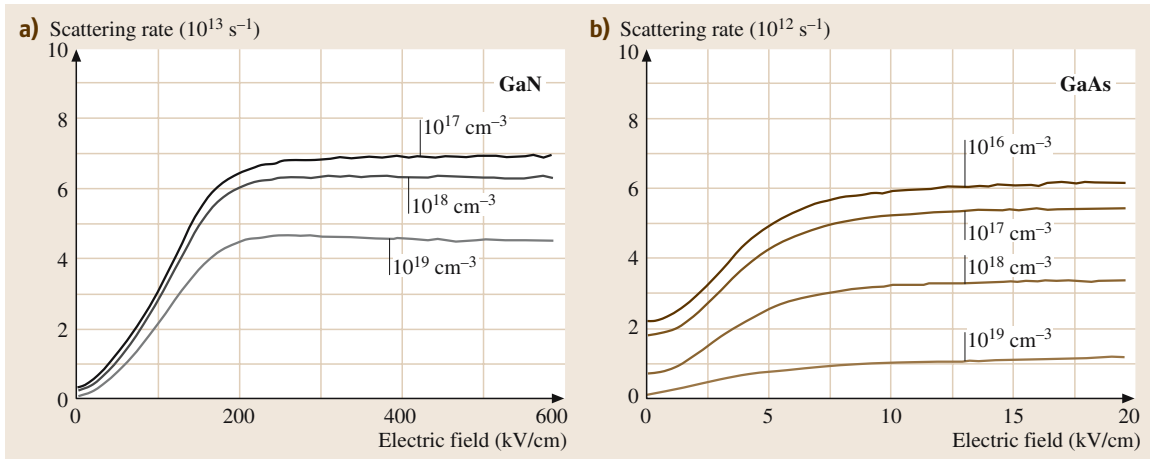

Fig. 33.11a,b A comparison of the polar optical phonon scattering rates as a function of the applied electric field, for both (a) GaN and (b) GaAs, for various doping concentrations

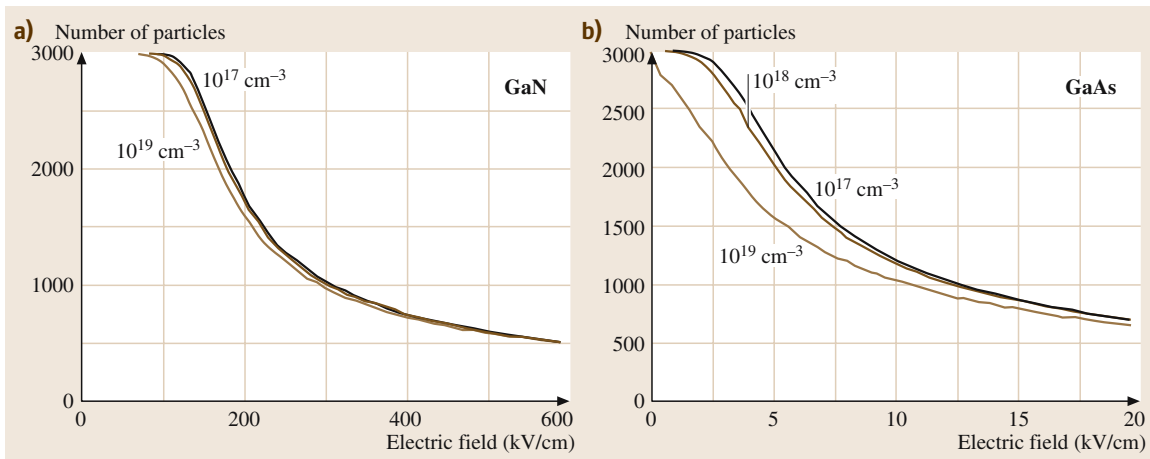

Fig. 33.12a,b A comparison of the number of particles in the lowest valley of the conduction band, the Γ valley, as a function of the applied electric field, for both (a) GaN and (b) GaAs, for various doping concentration levels. Three thousand electrons were employed for these steady-state electron transport simulations

33.2.5 Electron Transport in AlN

AlN has the largest effective mass of the III–V nitride semiconductors considered in this analysis. Accordingly, it is not surprising that this material exhibits the lowest electron drift velocity and the lowest low-field electron drift mobility. The sensitivity of the velocity–field characteristic associated with AlN to variations in the crystal temperature may be examined by considering Fig. 33.13. As with the case of GaN, the velocity–field characteristic associated with AlN is extremely robust to variations in the crystal tem-

perature. In particular, its peak electron drift velocity, which is $1.8 \times 10^7 \text{ cm/s}$ at 100 K, only decreases to $1.2 \times 10^7 \text{ cm/s}$ at 700 K. Similarly, its saturation electron drift velocity, which is $1.5 \times 10^7 \text{ cm/s}$ at 100 K, only decreases to $1.0 \times 10^7 \text{ cm/s}$ at 700 K. The low-field electron drift mobility associated with AlN also diminishes in response to increases in the crystal temperature, from $375 \text{ cm}^2/\text{Vs}$ at 100 K to $40 \text{ cm}^2/\text{Vs}$ at 700 K.

The sensitivity of the velocity–field characteristic associated with AlN to variations in the doping concentration may be examined by considering Fig. 33.14. It

Fig. 33.13a,b The velocity–field characteristic associated with AlN (a) for various crystal temperatures. The trends in the low-field mobility (solid line), the peak electron drift velocity (diamonds), and the saturation electron drift velocity (solid points), are also shown. AlN exhibits its peak electron drift velocity at very high applied electric fields. AlN has the lowest peak electron drift velocity and the lowest low-field electron drift mobility of the III–V nitride semiconductors considered in this analysis (b)

Fig. 33.14a,b The velocity–field characteristic associated with AlN for various doping concentrations (a). The trends in the low-field electron drift mobility (solid line), the peak electron drift velocity (diamonds), and the saturation electron drift velocity (solid points), are also shown (b)

is noted that the variations in the velocity–field characteristic associated with AlN in response to variations in the doping concentration are not as pronounced as those which occur in response to variations in the crystal temperature. Quantitatively, the peak electron drift velocity drops from 1.7×10^7 cm/s at 10^{17} cm^{-3} doping to 1.3×10^7 cm/s at 10^{19} cm^{-3} doping. Similarly, its saturation electron drift velocity drops from

1.4×10^7 cm/s at 10^{17} cm^{-3} doping to 1.2×10^7 cm/s at 10^{19} cm^{-3} doping. The influence of doping on the low-field electron drift mobility associated with AlN is also observed to be not as pronounced as for the case of crystal temperature. Figure 33.14b shows that the low-field electron drift mobility associated with AlN decreases from $140 \text{ cm}^2/\text{Vs}$ at 10^{16} cm^{-3} doping to $100 \text{ cm}^2/\text{Vs}$ at 10^{19} cm^{-3} doping.

Fig. 33.15a,b The velocity–field characteristic associated with InN for various crystal temperatures (a). The trends in the low-field electron drift mobility (solid line), the peak electron drift velocity (diamonds), and the saturation electron drift velocity (solid points), are also shown. (b) InN has the highest peak electron drift velocity and the highest low-field electron drift mobility of the III–V nitride semiconductors considered in this analysis

33.2.6 Electron Transport in InN

InN has the smallest effective mass of the three III–V nitride semiconductors considered in this analysis. Accordingly, it is not surprising that it exhibits the highest electron drift velocity and the highest low-field electron drift mobility. The sensitivity of the velocity–field characteristic associated with InN to variations in the crystal temperature may be examined by consider-

ing Fig. 33.15. As with the cases of GaN and AlN, the velocity–field characteristic associated with InN is extremely robust to increases in the crystal temperature. In particular, its peak electron drift velocity, which is 4.4×10^7 cm/s at 100 K, only decreases to 3.2×10^7 cm/s at 700 K. Similarly, its saturation electron drift velocity, which is 2.0×10^7 cm/s at 100 K, only decreases to 1.5×10^7 cm/s at 700 K. The low-field electron drift mobility associated with InN also

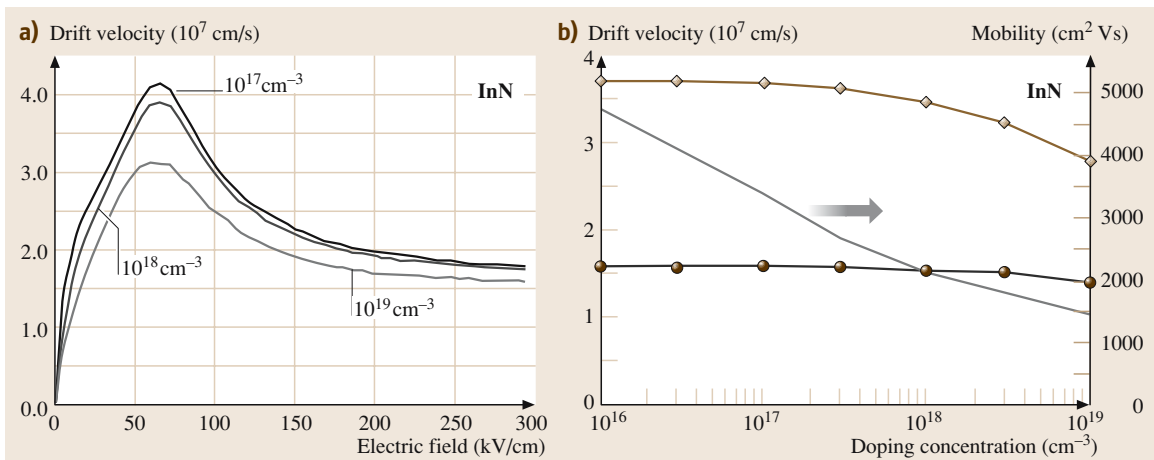

Fig. 33.16a,b The velocity–field characteristic associated with InN for various doping concentrations (a). The trends in the low-field electron drift mobility (solid line), the peak electron drift velocity (diamonds), and the saturation electron drift velocity (solid points), are also shown (b)

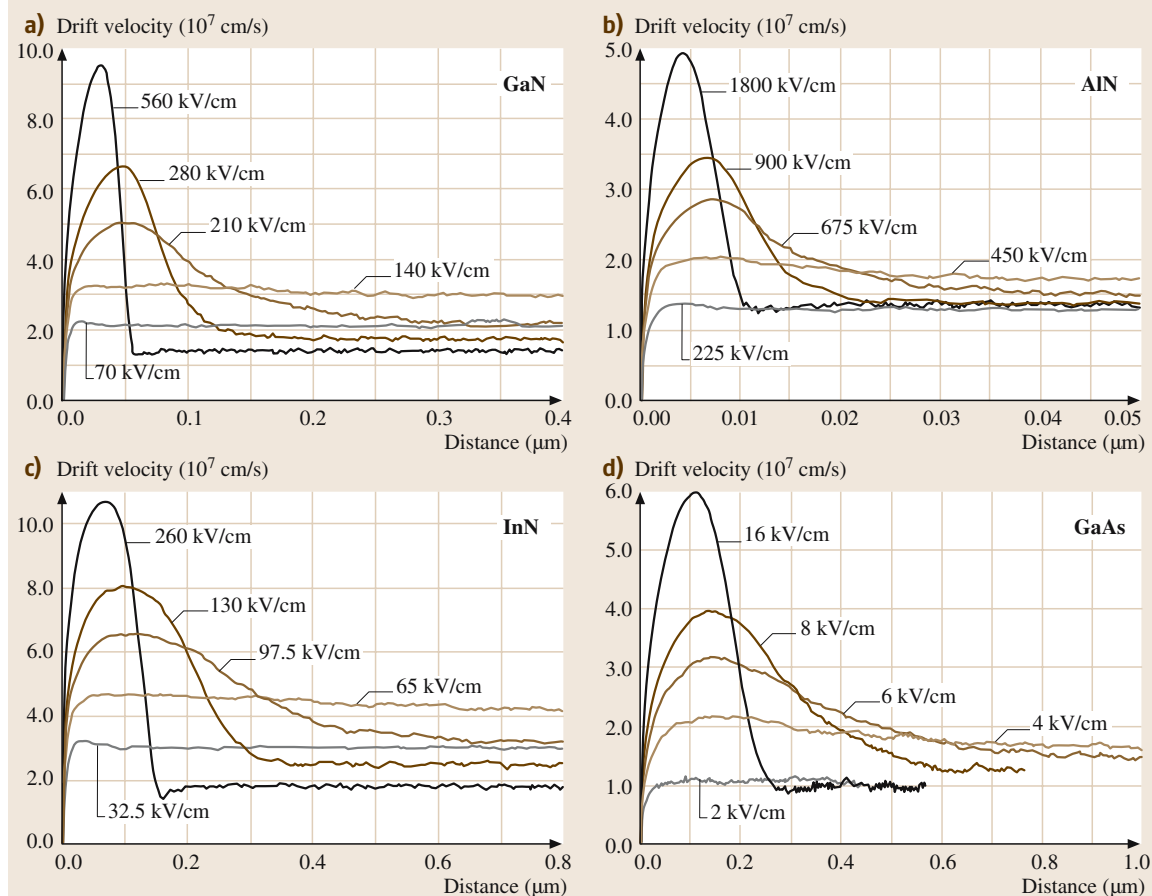

Fig. 33.17a–d The electron drift velocity as a function of the distance displaced since the application of the electric field for various applied electric field strengths, for the cases of (a) GaN, (b) AlN, (c) InN, and (d) GaAs. In all cases, we have assumed an initial zero field electron distribution, a crystal temperature of 300 K, and a doping concentration of 10^{17} cm^{-3} . After [33.29] with permission, copyright AIP

diminishes in response to increases in the crystal temperature, from about $9000 \text{ cm}^2/\text{Vs}$ at 100 K to below $1000 \text{ cm}^2/\text{Vs}$ at 700 K.

The sensitivity of the velocity–field characteristic associated with InN to variations in the doping concentration may be examined by considering Fig. 33.16. These results suggest a similar robustness to the doping concentration for the case of InN. In particular, it is noted that for doping concentrations below 10^{17} cm^{-3} , the velocity–field characteristic associated with InN exhibits very little dependence on the doping concentration. When the doping concentration is increased above 10^{17} cm^{-3} , however, the peak electron drift velocity diminishes. Quantitatively, the peak electron drift velocity decreases from $4.1 \times 10^7 \text{ cm/s}$ at 10^{17} cm^{-3} doping to

$3.2 \times 10^7 \text{ cm/s}$ at 10^{19} cm^{-3} doping. The saturation electron drift velocity only drops slightly, however, from $1.8 \times 10^7 \text{ cm/s}$ at 10^{17} cm^{-3} doping to $1.5 \times 10^7 \text{ cm/s}$ at 10^{19} cm^{-3} doping. The low-field electron drift mobility, however, drops significantly with doping, from $4700 \text{ cm}^2/\text{Vs}$ at 10^{16} cm^{-3} doping to $1500 \text{ cm}^2/\text{Vs}$ at 10^{19} cm^{-3} doping.

33.2.7 Transient Electron Transport

Steady-state electron transport is the dominant electron transport mechanism in devices with larger dimensions. For devices with smaller dimensions, however, transient electron transport must also be considered when evaluating device performance. *Ruch* [33.57] demonstrated,

for both silicon and GaAs, that the transient electron drift velocity may exceed the corresponding steady-state electron drift velocity by a considerable margin for appropriate selections of the applied electric field. *Shur and Eastman* [33.58] explored the device implications of transient electron transport, and demonstrated that substantial improvements in the device performance can be achieved as a consequence. *Heiblum et al.* [33.59] made the first direct experimental observation of transient electron transport within GaAs. Since then there have been a number of experimental investigations into the transient electron transport within the III–V compound semiconductors; see, for example, [33.60–62].

Thus far, very little research has been invested into the study of transient electron transport within the III–V nitride semiconductors, GaN, AlN, and InN. *Foutz et al.* [33.21] examined transient electron transport within both the wurtzite and zinc blende phases of GaN. In particular, they examined how electrons, initially in thermal equilibrium, respond to the sudden application of a constant electric field. In devices with dimensions greater than $0.2\ \mu\text{m}$, they found that steady-state electron transport is expected to dominate device performance. For devices with smaller dimensions, however, upon the application of a sufficiently high electric field, they found that the transient electron drift velocity can considerably overshoot the corresponding steady-state electron drift velocity. This velocity overshoot was found to be comparable with that which occurs within GaAs.

Foutz et al. [33.29] performed a subsequent analysis in which the transient electron transport within all of the III–V nitride semiconductors under consideration in this analysis were compared with that which occurs within GaAs. In particular, following the approach of *Foutz et al.* [33.21], they examined how electrons, initially in thermal equilibrium, respond to the sudden application of a constant electric field. A key result of this study, presented in Fig. 33.17, plots the transient electron drift velocity as a function of the distance displaced since the electric field was initially applied for a number of applied electric field strengths and for each of the materials considered in this analysis.

Focusing initially on the case of GaN (Fig. 33.17a), we note that the electron drift velocity for the applied electric field strengths $70\ \text{kV/cm}$ and $140\ \text{kV/cm}$ reaches steady-state very quickly, with little or no velocity overshoot. In contrast, for applied electric field strengths above $140\ \text{kV/cm}$, significant velocity overshoot occurs. This result suggests that in GaN,

$140\ \text{kV/cm}$ is a critical field for the onset of velocity overshoot effects. As mentioned in Sect. 33.2.2, $140\ \text{kV/cm}$ also corresponds to the peak in the velocity-field characteristic associated with GaN; recall Fig. 33.4. Steady-state Monte Carlo simulations suggest that this is the point at which significant upper valley occupation begins to occur; recall Fig. 33.3. This suggests that velocity overshoot is related to the transfer of electrons to the upper valleys. Similar results are found for the other III–V nitride semiconductors, AlN and InN, and GaAs; see Figs. 33.17b–d.

We now compare the transient electron transport characteristics for the materials. From Fig. 33.17, it is clear that certain materials exhibit higher peak overshoot velocities and longer overshoot relaxation times. It is not possible to fairly compare these different semiconductors by applying the same applied electric field strength to each of the materials, as the transient effects occur over such a disparate range of applied electric field strengths in each material. In order to facilitate such a comparison, we choose a field strength equal to twice the critical applied electric field strength for each material. Figure 33.18 shows a comparison of the velocity overshoot effects amongst the four materials considered in this analysis, i.e., GaN, AlN, InN, and

Fig. 33.18 A comparison of the velocity overshoot amongst the III–V nitride semiconductors and GaAs. The applied electric field strength chosen corresponds to twice the critical applied electric field strength at which the peak in the steady-state velocity–field characteristic occurs (Fig. 33.4), i.e., $280\ \text{kV/cm}$ for the case of GaN, $900\ \text{kV/cm}$ for the case of AlN, $130\ \text{kV/cm}$ for the case of InN, and $8\ \text{kV/cm}$ for the case of GaAs. After [33.29] with permission, copyright AIP

GaAs. It is clear that among the three III–V nitride semiconductors considered, InN exhibits superior transient electron transport characteristics. In particular, InN has the largest overshoot velocity and the distance over which this overshoot occurs, $0.3\text{ }\mu\text{m}$, is longer than in either GaN and AlN. GaAs exhibits a longer overshoot relaxation distance, approximately $0.7\text{ }\mu\text{m}$, but the electron drift velocity exhibited by InN is greater than that of GaAs for all distances.

33.2.8 Electron Transport: Conclusions

In this section, steady-state and transient electron transport results, corresponding to the III–V nitride semiconductors, GaN, AlN, and InN, were presented, these results being obtained from our Monte Carlo simulations of the electron transport within these materials.

Steady-state electron transport was the dominant theme of our analysis. In order to aid in the understanding of these electron transport characteristics, a comparison was made between GaN and GaAs. Our simulations showed that GaN is more robust to variations in crystal temperature and doping concentration than GaAs, and an analysis of our Monte Carlo simulation results showed that polar optical phonon scattering plays the dominant role in accounting for these differences in behavior. This analysis was also performed for the other III–V nitride semiconductors considered in this analysis – AlN and InN – and similar results were obtained. Finally, we presented some key transient electron transport results. These results indicated that the transient electron transport that occurs within InN is the most pronounced of all of the materials under consideration in this review (GaN, AlN, InN, and GaAs).

33.3 Electron Transport Within III–V Nitride Semiconductors: A Review

Pioneering investigations into the material properties of the III–V nitride semiconductors, GaN, AlN, and InN, were performed during the earlier half of the twentieth century [33.63–65]. The III–V nitride semiconductor materials available at the time, small crystals and powders, were of poor quality, and completely unsuitable for device applications. Thus, it was not until the late 1960s, when *Maruska* and *Tietjen* [33.66] employed chemical vapor deposition to fabricate GaN, that interest in the III–V nitride semiconductors experienced a renaissance. Since that time, interest in the III–V nitride semiconductors has been growing, the material properties of these semiconductors improving considerably over the years. As a result of this research effort, there are currently a number of commercial devices available that employ the III–V nitride semiconductors. More III–V nitride semiconductor-based device applications are currently under development, and these should become available in the near future.

In this section, we present a brief overview of the III–V nitride semiconductor electron transport field. We start with a survey describing the evolution of the field. In particular, the sequence of critical developments that have occurred that contribute to our current understanding of the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN, is chronicled. Then, some of the current literature is presented, with particular emphasis being placed on the most recent developments in the field and how such

developments are modifying our understanding of the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN. Finally, frontiers for further research and investigation are presented.

This section is organized in the following manner. In Sect. 33.3.1, we present a brief survey describing the evolution of the field. Then, in Sect. 33.3.2, the current literature is discussed. Finally, frontiers for further research and investigation are presented in Sect. 33.3.3.

33.3.1 Evolution of the Field

The favorable electron transport characteristics of the III–V nitride semiconductors, GaN, AlN, and InN, have long been recognized. As early as the 1970s, *Littlejohn et al.* [33.13] pointed out that the large polar optical phonon energy characteristic of GaN, in conjunction with its large intervalley energy separation, suggests a high saturation electron drift velocity for this material. As the high-frequency electron device performance is, to a large degree, determined by this saturation electron drift velocity [33.14], the recognition of this fact ignited enhanced interest in this material and its III–V nitride semiconductor compatriots, AlN and InN. This enhanced interest, and the developments which have transpired as a result of it, are responsible for the III–V nitride semiconductor industry of today.

In 1975, *Littlejohn et al.* [33.13] were the first to report results obtained from semi-classical Monte Carlo

simulations of the steady-state electron transport within bulk wurtzite GaN. A one-valley model for the conduction band was adopted in their analysis. Steady-state electron transport, for both parabolic and nonparabolic band structures, was considered in their analysis, nonparabolicity being treated through the application of the Kane model [33.43]. The primary focus of their investigation was the determination of the velocity-field characteristic associated with GaN. All donors were assumed to be ionized, and the free electron concentration was taken to be equal to the dopant concentration. The scattering mechanisms considered were (1) ionized impurity, (2) polar optical phonon, (3) piezoelectric, and (4) acoustic deformation potential. For the case of the parabolic band, in the absence of ionized impurities, they found that the electron drift velocity monotonically increases with the applied electric field strength, saturating at a value of about 2.5×10^7 cm/s for the case of high applied electric fields. In contrast, for the case of the nonparabolic band, and in the absence of ionized impurities, a region of negative differential mobility was found, the electron drift velocity achieving a maximum of about 2×10^7 cm/s at an applied electric field strength of about 100 kV/cm, with further increases in the applied electric field strength resulting in a slight decrease in the corresponding electron drift velocity. The role of ionized impurity scattering was also investigated by *Littlejohn et al.* [33.13].

In 1993, *Gelmont et al.* [33.16] reported on ensemble semi-classical two-valley Monte Carlo simulations of the electron transport within bulk wurtzite GaN, this analysis improving upon the analysis of *Littlejohn et al.* [33.13] by incorporating intervalley scattering into the simulations. They found that the negative differential mobility found in bulk wurtzite GaN is much more pronounced than that found by *Littlejohn et al.* [33.13], and that intervalley transitions are responsible for this. For a doping concentration of 10^{17} cm⁻³, *Gelmont et al.* [33.16] demonstrated that the electron drift velocity achieves a peak value of about 2.8×10^7 cm/s at an applied electric field of about 140 kV/cm. The impact of intervalley transitions on the electron distribution function was also determined and shown to be significant. The impact of doping and compensation on the velocity-field characteristic associated with bulk wurtzite GaN was also examined.

Since these pioneering investigations, ensemble Monte Carlo simulations of the electron transport within GaN have been performed numerous times. In particular, in 1995 *Mansour et al.* [33.18] reported the use of such an approach in order to determine how the crystal

temperature influences the velocity-field characteristic associated with bulk wurtzite GaN. Later that year, *Kolník et al.* [33.19] reported on employing full-band Monte Carlo simulations of the electron transport within bulk wurtzite GaN and bulk zinc blende GaN, finding that bulk zinc blende GaN exhibits a much higher low-field electron drift mobility than bulk wurtzite GaN. The peak electron drift velocity corresponding to bulk zinc blende GaN was found to be only marginally greater than that exhibited by bulk wurtzite GaN. In 1997, *Bhaskar and Shur* [33.22] reported on employing ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within bulk and confined wurtzite GaN. Their simulations demonstrated that the two-dimensional electron gas within a confined wurtzite GaN structure will exhibit a higher low-field electron drift mobility than bulk wurtzite GaN, by almost an order of magnitude, this being in agreement with experiment. In 1998, *Albrecht et al.* [33.27] reported on employing ensemble semi-classical five-valley Monte Carlo simulations of the electron transport within bulk wurtzite GaN, with the aim of determining elementary analytical expressions for a number of electron transport metrics corresponding to bulk wurtzite GaN, for the purposes of device modeling.

Electron transport within the other III–V nitride semiconductors, AlN and InN, has also been studied using ensemble semi-classical Monte Carlo simulations of the electron transport. In particular, by employing ensemble semi-classical three-valley Monte Carlo simulations, the velocity-field characteristic associated with bulk wurtzite AlN was studied and reported by *O'Leary et al.* [33.24] in 1998. They found that AlN exhibits the lowest peak and saturation electron drift velocities of the III–V nitride semiconductors considered in this analysis. Similar simulations of the electron transport within bulk wurtzite AlN were also reported by *Albrecht et al.* [33.25] in 1998. The results of *O'Leary et al.* [33.24] and *Albrecht et al.* [33.25] were found to be quite similar. The first known simulation of the electron transport within bulk wurtzite InN was the semi-classical three-valley Monte Carlo simulation of *O'Leary et al.* [33.23], reported in 1998. InN was demonstrated to have the highest peak and saturation electron drift velocities of the III–V nitride semiconductors. The subsequent ensemble full-band Monte Carlo simulations of *Bellotti et al.* [33.28], reported in 1999, produced results similar to those of *O'Leary et al.* [33.23].

The first known study of transient electron transport within the III–V nitride semiconductors was that performed by *Foutz et al.* [33.21], reported in 1997. In

this study, ensemble semi-classical three-valley Monte Carlo simulations were employed in order to determine how the electrons within wurtzite and zinc blende GaN, initially in thermal equilibrium, respond to the sudden application of a constant electric field. The velocity overshoot that occurs within these materials was examined. It was found that the electron drift velocities that occur within the zinc blende phase of GaN are slightly greater than those exhibited by the wurtzite phase owing to the slightly higher steady-state electron drift velocity exhibited by the zinc blende phase of GaN. A comparison with the transient electron transport that occurs within GaAs was made. Using the results from this analysis, a determination of the minimum transit time as a function of the distance displaced since the application of the applied electric field was performed for all three materials considered in this study: wurtzite GaN, zinc blende GaN, and GaAs. For distances in excess of 0.1 μm , both phases of GaN were shown to exhibit superior performance (reduced transit time) when contrasted with that associated with GaAs.

A more general analysis, in which transient electron transport within GaN, AlN, and InN was studied, was performed by Foutz et al. [33.29], and reported in 1999. As with their previous study, Foutz et al. [33.29] determined how electrons, initially in thermal equilibrium, respond to the sudden application of a constant electric field. For GaN, AlN, InN, and GaAs, it was found that the electron drift velocity overshoot only occurs when the applied electric field exceeds a certain critical applied electric field strength unique to each material. The critical applied electric field strengths, 140 kV/cm for the case of wurtzite GaN, 450 kV/cm for the case of AlN, 65 kV/cm for the case of InN, and 4 kV/cm for the case of GaAs, were shown to correspond to the peak electron drift velocity in the velocity-field characteristic associated with each of these materials; recall Fig. 33.4. It was found that InN exhibits the highest peak overshoot velocity, and that this overshoot lasts over prolonged distances compared with AlN, InN, and GaAs. A comparison with the results of experiment was performed.

In addition to Monte Carlo simulations of the electron transport within these materials, a number of other types of electron transport studies have been performed. In 1975, for example, Ferry [33.14] reported on the determination of the velocity-field characteristic associated with wurtzite GaN using a displaced Maxwellian distribution function approach. For high applied electric fields, Ferry [33.14] found that the electron drift velocity associated with GaN monotonically increases

with the applied electric field strength (it does not saturate), reaching a value of about 2.5×10^7 cm/s at an applied electric field strength of 300 kV/cm. The device implications of this result were further explored by Das and Ferry [33.15]. In 1994, Chin et al. [33.17] reported on a detailed study of the dependence of the low-field electron drift mobilities associated with the III–V nitride semiconductors, GaN, AlN, and InN, on crystal temperature and doping concentration. An analytical expression for the low-field electron drift mobility, μ , determined using a variational principle, was used for the purposes of this analysis. The results obtained were contrasted with those from experiment. A subsequent mobility study was reported in 1997 by Look et al. [33.38]. Then, in 1998, Weimann et al. [33.26] reported on a model for determining how the scattering of electrons by the threading dislocations within bulk wurtzite GaN influence the low-field electron drift mobility. They demonstrated why the experimentally measured low-field electron drift mobility associated with this material is much lower than that predicted from Monte Carlo analyses: threading dislocations were not taken into account in the Monte Carlo simulations of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN.

While the negative differential mobility exhibited by the velocity-field characteristics associated with the III–V nitride semiconductors, GaN, AlN, and InN, is widely attributed to intervalley transitions, and while direct experimental evidence confirming this has been presented [33.67], Krishnamurthy et al. [33.34] suggest that the inflection points in the bands located in the vicinity of the Γ valley are primarily responsible for the negative differential mobility exhibited by wurtzite GaN instead. The relative importance of these two mechanisms (intervalley transitions and inflection point considerations) were evaluated by Krishnamurthy et al. [33.34], for both bulk wurtzite GaN and an AlGaIn alloy.

33.3.2 Recent Developments

There have been a number of interesting recent developments in the study of the electron transport within the III–V nitride semiconductors which have influenced the direction of thought in this field. On the experimental front, in 2000 Wraback et al. [33.33] reported on the use of a femtosecond optically detected time-of-flight experimental technique in order to experimentally determine the velocity-field characteristic associated with bulk wurtzite GaN. They found that the peak electron

drift velocity, 1.9×10^7 cm/s, is achieved at an applied electric field strength of 225 kV/cm. No discernible negative differential mobility was observed. *Wraback et al.* [33.33] suggested that the large defect density characteristic of the GaN samples they employed, which were not taken into account in Monte Carlo simulations of the electron transport within this material, accounts for the difference between this experimental result and that obtained using simulation. They also suggested that decreasing the intervalley energy separation from about 2 eV to 340 meV, as suggested by the experimental results of *Brazel et al.* [33.56], may also account for these observations.

The determination of the electron drift velocity from experimental measurements of the unity gain cut-off frequency, f_t , has been pursued by a number of researchers. The key challenge in these analyses is the de-embedding of the parasitics from the experimental measurements so that the true intrinsic saturation electron drift velocity may be obtained. *Eastman et al.* [33.68] present experimental evidence which suggests that the saturation electron drift velocity within bulk wurtzite GaN is about 1.2×10^7 – 1.3×10^7 cm/s. A more recent report, by *Oxley and Uren* [33.69], suggests a value of 1.1×10^7 cm/s. The role of self-heating was also probed by *Oxley and Uren* [33.69] and shown to be relatively insignificant. A completely satisfactory explanation for the discrepancy between these results and those from the Monte Carlo simulations has yet to be provided.

Wraback et al. [33.70] performed a subsequent study on the transient electron transport within wurtzite GaN. In particular, using their femtosecond optically detected time-of-flight experimental technique in order to experimentally determine the velocity overshoot that occurs within bulk wurtzite GaN, they observed substantial velocity overshoot within this material. In particular, a peak transient electron drift velocity of 7.25×10^7 cm/s was observed within the first 200 fs after photoexcitation for an applied electric field strength of 320 kV/cm. These experimental results were shown to be consistent with the theoretical predictions of *Foutz et al.* [33.29].

On the theoretical front, there have been a number of recent developments. In 2001, *O'Leary et al.* [33.30] presented an elementary, one-dimensional analytical model for the electron transport within the III–V compound semiconductors, and applied it to the cases of wurtzite GaN and GaAs. The predictions of this analytical model were compared with those of Monte Carlo simulations and were found to be in satisfactory agreement. Hot-electron energy relaxation times within the III–V nitride semiconductors were recently studied by *Matulionis*

et al. [33.71] and reported in 2002. *Bulutay et al.* [33.72] studied the electron momentum and energy relaxation times within the III–V nitride semiconductors and reported the results of this study in 2003. It is particularly interesting to note that their arguments add considerable credence to the earlier inflection point argument of *Krishnamurthy et al.* [33.34]. In 2004, *Brazis and Raguotis* [33.73] reported on the results of a Monte Carlo study involving additional phonon modes and a smaller intervalley energy separation for bulk wurtzite GaN. Their results were found to be much closer to the experimental results of *Wraback et al.* [33.33] than those found previously.

The influence of hot-phonons on the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN, has been the focus of considerable recent investigation. In particular, in 2004 *Silva and Nascimento* [33.74], *Gökden* [33.75], and *Ridley et al.* [33.76], to name just three, presented results related to this research focus. These results suggest that hot-phonon effects play a significant role in influencing the nature of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN. In particular, *Ridley et al.* [33.76] point out that the saturation electron drift velocity and the applied electric field strength at which the peak in the velocity–field characteristic occurs are both influenced by hot-phonon effects. The role that hot-phonons play in influencing device performance was studied by *Matulionis and Liberis* [33.77]. Research into the role that hot-phonons play in influencing the electron transport mechanisms within the III–V nitride semiconductors, GaN, AlN, and InN, seems likely to continue into the foreseeable future.

33.3.3 Future Perspectives

It is clear that our understanding of the electron transport within the III–V nitride semiconductors, GaN, AlN, and InN, is, at present at least, in a state of flux. A complete understanding of the electron transport mechanisms within these materials has yet to be achieved, and is the subject of intense current research. Most troubling is the discrepancy between the results of experiment and those of simulation. There are two principal sources of uncertainty in our analysis of the electron transport mechanisms within these materials: (1) uncertainty in the material properties, and (2) uncertainty in the underlying physics. We discuss each of these subsequently.

Uncertainty in the material parameters associated with the III–V nitride semiconductors, GaN, AlN, and

InN, remains a key source of ambiguity in the analysis of the electron transport with these materials [33.32]. Even for bulk wurtzite GaN, the most studied of the III–V nitride semiconductors considered in this analysis, uncertainty in the band structure remains an issue [33.56]. The energy gap associated with InN and the effective mass associated with this material continue to fuel debate; see, for example, *Davydov et al.* [33.53], *Wu et al.* [33.54], and *Matsuoka et al.* [33.55]. Variations in the experimentally determined energy gap associated with InN, observed from sample to sample, further confound matters. Most recently, *Shubina et al.* [33.78] suggested that nonstoichiometry within InN may be responsible for these variations in the energy gap. Further research will have to be performed in order to confirm this. Given this uncertainty in the band structures associated with the III–V nitride semiconductors, it is

clear that new simulations of the electron transport will have to be performed once researchers have settled on the appropriate band structures. We thus view our present results as a baseline, the sensitivity analysis of *O’Leary et al.* [33.32] providing some insights into how variations in the band structures will impact upon the results.

Uncertainty in the underlying physics is considerable. The source of the negative differential mobility remains a matter to be resolved. The presence of hot-phonons within these materials, and how such phonons impact upon the electron transport mechanisms within these materials, remains another point of contention. It is clear that a deeper understanding of these electron transport mechanisms will have to be achieved in order for the next generation of III–V nitride semiconductor-based devices to be properly designed.

33.4 Conclusions

In this paper, we reviewed analyses of the electron transport within the III–V nitride semiconductors GaN, AlN, and InN. In particular, we have discussed the evolution of the field, surveyed the current literature, and presented frontiers for further investigation and analysis. In order to narrow the scope of this review, we focused on the electron transport within bulk wurtzite GaN, AlN, and InN for the purposes of this paper. Most of our discussion focused upon results obtained from our ensemble semi-classical three-valley Monte Carlo simulations of the electron transport within these materials, our results conforming with state-of-the-art III–V nitride semiconductor orthodoxy.

We began our review with the Boltzmann transport equation, since this equation underlies most analy-

ses of the electron transport within semiconductors. A brief description of our ensemble semi-classical three-valley Monte Carlo simulation approach to solving the Boltzmann transport equation was then provided. The material parameters, corresponding to bulk wurtzite GaN, AlN, and InN, were then presented. We then used these material parameter selections, and our ensemble semi-classical three-valley Monte Carlo simulation approach, to determine the nature of the steady-state and transient electron transport within the III–V nitride semiconductors. Finally, we presented some recent developments on the electron transport within these materials, and pointed to fertile frontiers for further research and investigation.

34. II–IV Semiconductors for Optoelectronics: CdS, CdSe, CdTe

Owing to their suitable band gaps and high absorption coefficients, Cd-based compounds such as CdTe and CdS are the most promising photovoltaic materials available for low-cost high-efficiency solar cells. Additionally, because of their large atomic number, Cd-based compounds such as CdTe and CdZnTe, have been applied to radiation detectors. For these reasons, preparation techniques for these materials in the polycrystalline films and bulk single crystals demanded by these devices have advanced significantly in recent decades, and practical applications have been realized in optoelectronic devices. This chapter mainly describes the application of these materials in solar cells and radiation detectors and introduces recent progress.

34.1 Background

Cd-based compounds are very important semiconductor materials in the II–VI family. The attraction of Cd-based binary and ternary compounds arises from their promis-

ing applications as solar cells, γ - and X-ray detectors etc. These devices made from Cd-based materials are being widely applied in many fields.

34.2 Solar Cells

With the development of human society, energy sources in the earth are being slowly exhausted and we are faced with a serious problem. The solar cell is one substitute for fossil fuels and is being realized throughout the world. For this reason, solar-cell technologies have been developed since work was started by *Becquerel* in 1839 [34.1]. The solar cell has now been applied to daily life, industry, agriculture, space exploration, military affairs etc.

Solar cells have many advantages. Firstly, sunlight as an energy source for power generation is not only limitless but can be used freely. Secondly, since light is

directly converted to electricity, the conversion process is clean, noise-free and not harmful to the environment, unlike a mechanical power generator. Thirdly, solar cells need little maintenance.

34.2.1 Basic Description of Solar Cells

A solar cell is a semiconductor device that directly converts light energy into electrical energy through the photovoltaic process. The basic structure of a solar cell is shown in Fig. 34.1. A typical solar cell consists of a junction formed between an n-type and a p-type

Fig. 34.1 The principle of photovoltaic devices

semiconductor, of the same (homojunction) or different materials (heterojunction), an antireflection coating and Ohmic collecting electrodes. When the light irradiates the surface of a solar cell, photons with an energy greater than the band gap of the semiconductor are absorbed by the semiconductor material. This absorption activates electron transitions from the valence to the conduction band, so that electron–hole pairs are generated. If these carriers can diffuse into the depletion region before they recombine, they can be separated by the applied electric field. At the p–n junction, the negative electrons diffuse into the n-type region and the positive holes diffuse into the p-type region. They are then collected by electrodes, resulting in a voltage difference between the two electrodes. When an external load is connected, electric current flows through the load. This is the origin of the solar cell's photocurrent.

Three parameters can be used to describe the performance of a solar cell: the short-circuit current density (J_{SC}), the open-circuit voltage (V_{OC}) and the fill factor (FF).

The short-circuit current density J_{SC} is the photocurrent output from a solar cell when the output terminals are short-circuited. In the ideal case, this is equal to the current density generated by the light J_L and is proportional to the incident photon flux. J_{SC} is determined by the spectral response of the device, the junction depth, and the series (internal) resistance, R_s . The open-circuit voltage V_{OC} is the voltage appearing across the output terminals of the cell when there is no load present, i.e. when $J = 0$. The relationship between V_{OC} and J_{SC} can be described by the diode equation, i.e.:

$$V_{OC} = \frac{nkT}{e} \ln \left(\frac{J_{SC}}{J_0} + 1 \right), \quad (34.1)$$

Fig. 34.2 Photovoltaic output characteristics of a solar cell

where e , n , J_0 , k and T are the charge on an electron, the diode ideality factor, the reverse saturation-current density, the Boltzmann constant and the absolute temperature, respectively. The fill factor (FF) is the ratio of the maximum electrical power available from the cell [i.e. at the operating point J_m , V_m] in Fig. 34.2 to the product of V_{OC} and J_{SC} . It describes the rectangularity of the photovoltaic output characteristic.

$$FF = \frac{V_m \cdot J_m}{V_{oc} \cdot J_{sc}} = \frac{P_m}{V_{oc} \cdot J_{sc}}. \quad (34.2)$$

The conversion efficiency (η) of a solar cell is determined as

$$\eta = \frac{P_m}{P_s} = \frac{V_{oc} \cdot J_{sc} \cdot FF}{P_s}. \quad (34.3)$$

Where P_s is the incident illumination power and P_m is the output electricity power, both being per unit area. The relationship between the short-circuit current density J_{SC} and the open-circuit voltage V_{OC} is shown in Fig. 34.2.

34.2.2 Design of Cd-Based Solar Cells

Solar cells can be made from silicon (Si), III–V compounds such as GaAs, or II–VI compounds such as Zn-based and Cd-based compound semiconductors. Of these materials, CdTe is the most attractive because of a number of advantages. CdTe is a direct-band-gap material with a band gap of 1.54 eV at room temperature. This is very close to the theoretically calculated optimum value for solar cells. CdTe has a high absorption coefficient (above 10^5 cm^{-1} at a wavelength of 700 nm), so that approximately 90% of the incident light is absorbed by a layer thickness of only $2 \mu\text{m}$ (compared

Fig. 34.3 A typical CdS/CdTe solar cell

with around $10\ \mu\text{m}$ for Si), cutting down the quantity of semiconductor required. Therefore, CdTe is one of the most promising photovoltaic materials available for use in low-cost high-efficiency solar cells.

CdTe is the only material in which both n- and p-type conductivity can be easily controlled by doping acceptor or donor impurities in II–VI compound semiconductors. Furthermore, due to its high absorption coefficient and small carrier diffusion length, the junction must be formed close to the surface, which reduces the carrier lifetime through surface recombination. In spite of this, the conversion efficiency has been gradually enhanced from 4% [34.2] to 16% [34.3] since the first CdTe-based solar cell was fabricated. CdTe solar cells can be made from polycrystalline or single-crystal material. However, it was found that this p–n homojunction structure is unstable due to the aging behavior of dopants in CdTe films and bulk single crystals [34.4]. Furthermore, it is also difficult to fabricate shallow p–n junctions with highly conducting surface layers, and high surface recombination velocities led to substantial losses that could not easily be avoided. For this reason, the CdS/CdTe heterojunction solar cell was proposed.

It has been proved that CdS/CdTe is a high-efficiency heterojunction solar cell. The theoretical calculation shows that this cell has a conversion efficiency of as high as 29% [34.5], and it is considered a promising alternative to the more widely used silicon devices. The typical structure of a CdS/CdTe solar cell is glass/indium tin oxide (ITO)/CdS/CdTe/back electrode, as seen in Fig. 34.3. The CdS/CdTe solar cell is based on the heterojunction formed between n-type CdS (only n-CdS is available) and p-type CdTe and is fabricated in a superstrate configuration where the incident light passes through the glass substrate, which has a thickness of

2–4 mm. This window glass is transparent, strong and cheap. This glass substrate also protects the active layers from the environment, and it provides the mechanical strength of the device. The outer face of the panel often has an antireflection coating to enhance absorption efficiency. A transparent conducting oxide (TCO) layer, usually tin oxide or indium tin oxide (ITO), acts as the front contact to the device. This is needed to reduce the series resistance of the device, which would otherwise arise from the thinness of the CdS layer. Usually, the polycrystalline n-type CdS layer is deposited onto the TCO. Due to its wide band gap ($E_g \approx 2.4\ \text{eV}$ at 300 K) it is transparent down to wavelengths of around 516 nm. The thickness of this layer is typically 100–300 nm. The CdTe layer is p-type-doped and its thickness is typically around $10\ \mu\text{m}$. Generally, the carrier concentration in CdS layer is 2–3 orders greater than that of the CdTe layer. As a result, the potential is applied mostly to the CdTe absorber layer, i.e. the depletion region is mostly within the CdTe layer. Therefore, the photogenerated carriers can be effectively separated in this active region.

The electrode preparation is very important in obtaining Ohmic contact or minimal series resistivity. Since there are no metals with a work function higher than the hole affinity of p-type CdTe ($-5.78\ \text{eV}$) [34.6], it is difficult to produce a complete Ohmic contact on p-type CdTe surface. Many methods have been tried to fabricate Ohmic contact to p-type CdTe. Different metals or alloy and compounds such as Au, Al, and ZnTe/Cu etc. have also been used to serve as electrode materials. Although significant effort has been applied to this issue, the junction still inevitably displays some Schottky-diode characteristics. This is a problem that will be continuously studied.

34.2.3 Development of CdS/CdTe Solar Cells

The layers of CdS and CdTe for solar cells can be prepared using various techniques, which are summarized in Table 34.1. In these techniques, evaporation, close-space sublimation (CSS), screen printing and electrodeposition (ED) have been demonstrated to be very effective for fabricating high-efficiency large-area CdS/CdTe solar cells.

Study of solar cells based on CdTe single crystals and polycrystalline films were started as early as 1963 [34.7]. The cells were prepared with a p-type copper-telluride surface film as an integral part of the photovoltaic junction. The junction was thought to be a heterojunction between the p-type copper telluride and

Table 34.1 Some fabrication techniques and conversion efficiency of CdS/CdTe solar cells

Fabrication techniques of CdS and CdTe	Conversion efficiency	area	Reference
Evaporation: physical vapor deposition (PVD), and chemical vapor deposition (CVD)	11.8%	0.3 cm ²	[34.8]
Close-spaced sublimation (CSS)	16%	1.0 cm ²	[34.3]
	8.4%	7200 cm ²	[34.9]
Electrodeposition (ED)	14.2%	0.02 cm ²	[34.10]
Screen printing (SP) and sintering	12.8%	0.78 cm ²	[34.11]
Metalorganic CVD (MOCVD)	11.9%	0.08 cm ²	[34.12]
PVD vacuum evaporation	11.8%	0.3 cm ²	[34.8]
MBE	10.5%	0.08 cm ²	[34.13]
Sputtering deposition (SD)	14%	0.09 cm ²	[34.14]

the n-type CdTe, with the transition region extending well into the CdTe side. A similar structure was reported for single-crystal cells. A conversion efficiency of up to 6% was obtained in the film cells, and 7.5% for single-crystal cells.

Dutton and Muller [34.15] fabricated CdS/CdTe solar cells by standard vapor-deposition procedures with a very thin CdTe layer. The existence of the interfacial layer was confirmed using X-ray diffraction studies, and substantiated by diode photocurrent measurements. The results showed a threshold photon energy that corresponds to the band gap of CdTe. The thin CdTe layer resulted in excellent rectification ratios and high reverse breakdown voltages. The observed photoresponse, *I*–*V* (current versus voltage), and *C*–*V* (capacitance versus voltage) characteristics were consistence with those predicted by a semiconductor heterojunction model of the CdS–CdTe interface. Mitchell et al. [34.16] prepared a variety of CdS/CdTe heterojunction solar cells with an ITO coating and a glycerol antireflection coating by vacuum evaporation of n-CdS films onto single-crystal p-CdTe substrates. Comparisons were made between cells prepared using different substrate resistivity, substrate surface preparations, and CdS film resistivity. The mechanisms of controlling the dark junction current, photocarrier collection, and photovoltaic properties were modeled, taking account of the interface states of the junction. A conversion efficiency of 7.9% was obtained under 85 mW/cm² of solar simulator illumination.

At the end of the 1970s, a new process, screen printing and sintering, was developed for fabricating CdS/CdTe polycrystal solar cells by Matsushita and coworkers [34.11, 17–20]. This technique proved to be a very effective method for fabricating large-area CdS/CdTe film solar cells. There are several important parameters in the screen-printing technique: the viscos-

ity of the paste, the mesh number of the screen, the snap-off distance between the screen and the substrate and the pressure and speed of the squeegee. As cadmium chloride (CdCl₂) has a low melting point (*T*_m = 568 °C), and forms a eutectic with both CdS and CdTe at low temperature, and the vapor pressure at 600 °C is high enough to allow complete volatilization of CdCl₂ after the sintering process, CdCl₂ is used as an ideal flux for sintering both CdS and CdTe.

Nakayama et al. [34.18] prepared the first thin-film CdS/CdTe solar cells using the screen-printing technique (Fig. 34.4). A glass plate, which was coated successively with In₂O₃ film and CdS ceramic thin film, was used as a transparent Ohmic contact substrate. The n-type CdS film with a thickness of about 20 μm and a resistivity of 0.2 Ω cm was prepared on this substrate by the screen-printing method. The CdTe paste was printed onto the CdS layer using the same technique and then heat-treated in an N₂ atmosphere at temperatures of 500–800 °C. As a result, the p-type CdTe layer with a thickness of 10 μm showed a resistivity of 0.1–1 Ωcm. A silver (Ag) paste electrode was applied to the p-type

Fig. 34.4 Cross section of a ceramic thin-film CdTe solar cell

layer and an In–Ga alloy was applied to the CdS layer. The cell, with an active area of 0.36 cm^2 , showed an intrinsic solar conversion efficiency of 8.1% under an illumination of 140 mW/cm^2 solar simulator (AM0). Subsequently, this group continued to work on improving CdS/CdTe solar cells [34.11, 19, 20]. From the practical point of view, a modular solar cell is necessary. For this purpose, thin-film CdS/CdTe solar cells with an efficiency of 6.3% were prepared on a borosilicate-glass substrate of $4\times 4\text{ cm}^2$ by successively screen printing and heating (sintering) of each paste of CdS, CdTe and carbon [34.19]. Although they fabricated some structures, including dividing the CdTe film on one substrate into five small cells, to prevent increases in the series resistivity, a 1-watt module only showed an efficiency of 2.9% from 25 elemental cells with a $4\times 4\text{ cm}^2$ substrate. A main reason for this low efficiency was thought to be the high series resistivity.

In order to decrease the resistivity of the carbon electrode further, this group changed the heating conditions of the carbon electrodes for CdTe and examined the effect of impurities in the carbon paste on the characteristics of solar cells [34.11]. They found that the series resistance (R_s) and the conversion efficiency (η) of solar cells exhibited strong dependence on the oxygen (O_2) partial pressure during the heating process. The results showed that the addition of Cu to the carbon paste causes R_s and the diode factor (n) to decrease, resulting in a remarkable improvement in η . Using a low-resistance contact electrode, which was made from 50 ppm added Cu carbon paste, a cell with an active area of 0.78 cm^2 displayed $V_{oc} = 0.754\text{ V}$, $I_{sc} = 0.022\text{ A}$, $\text{FF} = 0.606$ and $\eta = 12.8\%$.

Britt and Ferekides [34.21] reported the fabrication and characteristics of high-efficiency thin-film CdS/CdTe heterojunction solar cells. CdS films with $0.07\text{--}0.10\text{ }\mu\text{m}$ in thickness were deposited on a $0.5\text{-}\mu\text{m}$

$\text{SnO}_2\text{:F}$ transparent conducting oxide layer by chemical-bath deposition and p-CdTe films with a thickness of $5\text{ }\mu\text{m}$ were deposited on the CdS layer by using the CSS method. Prior to the deposition of CdTe, CdS/ $\text{SnO}_2\text{:F}$ /glass was annealed in a H_2 atmosphere at temperatures of $350\text{--}425\text{ }^\circ\text{C}$ for 5–20 min. The characteristics of the CdS/CdTe solar cell were $V_{oc} = 843\text{ mV}$, $J_{sc} = 25.1\text{ mA/cm}^2$, $\text{FF} = 74.5\%$, corresponding to a total area greater than 1 cm^2 with an air mass 1.5 (AM1.5) conversion efficiency of 15.8%.

With modern growth techniques, high-efficiency CdS/CdTe solar cells have been developed using ultra-thin CdS films having a thickness of 50 nm [34.22]. Figure 34.5 shows the cross-sectional structure of a CdS/CdTe solar cell. CdS films were deposited on an ITO glass substrates by the metal organic chemical vapor deposition (MOCVD) technique, and CdTe films were subsequently deposited by the CSS technique (see Fig. 34.6) for the fabrication of CdS/CdTe solar cells. A thin-film CdS/CdTe solar cell with an area of 1.0 cm^2 under AM1.5 conditions showed $V_{oc} = 840\text{ mV}$, $J_{sc} = 26.08\text{ mA/cm}^2$ and $\text{FF} = 73\%$. As a result, a high conversion efficiency of 16.0% was achieved. Furthermore, they made developments in improving the uniformity of thickness and film qualities of CdS in order to obtain more efficient solar cells and to realize film deposition on large-area substrates of $30\times 60\text{ cm}$ or more [34.23]. They found clear differences in the electrical and optical properties between high- and low-quality CdS films. A photovoltaic conversion efficiency of 10.5% was achieved by a solar module with an area of 1376 cm^2 under AM1.5 measurement conditions.

Fig. 34.5 The cross-sectional structure of a CdS/CdTe solar cell fabricating by the screen-printing method

Fig. 34.6 Schematic of the close-spaced sublimation apparatus used for depositing CdTe films

In addition to dry processes such as screen printing, close-spaced sublimation etc., electrodeposition [34.24–27] has been also investigated for preparing polycrystalline CdTe layers for solar cells. *Awakura* and coworkers [34.25–27] reported the cathodic deposition behavior of CdTe thin layers under irradiation by visible light using ammoniacal basic aqueous solution as an electrolytic bath. Both deposition current density and current efficiency for the CdTe deposition were enhanced by irradiation. The deposited rate was over 10 times high than non-photoassisted electrodeposition. This was believed to represent significant progress in reducing the cost of Cd-based solar cells.

To date, solar cells with an n-CdS/p-CdTe heterojunction have been reported with efficiencies as high as 16% [34.22]. Recently, it was reported that thin-layered n-CdS/p-CdTe heterojunction solar cells have already been manufactured industrially [34.28]. n-CdS film with a thickness range of 500–1000 Å was deposited from an aqueous solution directly onto a transparent conductive oxide (TCO) substrate. After the CdS film was annealed for densification and grain growing, p-CdTe layer was formed by electrochemical deposition. The CdTe film was then annealed in air at 450 °C. Subsequently, monolithic TCO/CdS/CdTe was cut into discrete cells using an infrared laser. After other preparing process, a maximum efficiency of 10.6% for a CdTe 0.94-m² module with a power of 91.5 W was fabricated. The test results showed good stability. For practical applications, a 10-MW CdTe solar-cell manufacturing plant has been constructed [34.28].

34.2.4 CdZnTe Solar Cells

The ternary compound cadmium zinc telluride (CdZnTe, CZT) has potential for the preparation of high-efficiency tandem solar cell since its band gap can be tuned from 1.45 to 2.26 eV [34.29, 30]. *McCandless* et al. [34.29] deposited Cd_{1-x}Zn_xTe films using the physical vapor deposition (PVD) and vapor transport deposition (VTD) techniques. The film composition was between 0.35 and 0.6, corresponding to a band gap from 1.7 to 1.9 eV. Post-deposition treatment of CdZnTe films in ZnCl₂ vapor at 400 °C resulted in no change to

the alloy composition and caused recrystallization. Solar cells made from Cd_{1-x}Zn_xTe films with $x \approx 0.35$ exhibited $V_{oc} = 0.78$ V and $J_{sc} < 10$ mA/cm². These results were similar to those obtained from CdS window layers. Analysis of the spectral response indicated that Cd_{1-x}Zn_xTe with $x \approx 0.35$ has a band gap of about 1.7 eV. *Gidiputti* et al. [34.30] used two deposition technologies, co-sputtering from CdTe and ZnTe targets and co-close-spaced sublimation (CCSS) from CdTe and ZnTe powders, to prepare CdZnTe films. A structure similar to the CdTe superstrate configuration was initially utilized for cell fabrication: glass/ITO/CdS/CZT/graphite. Typical solar cell parameters obtained for CdZnTe/CdS (when $E_g(\text{CdZnTe}) = 1.72$ eV) solar cells were $V_{oc} = 720$ mV, and $J_{sc} = 2$ mA/cm². However, the spectral response indicated increasing loss of photocurrent at longer wavelengths. In order to improve the collection efficiency, CdZnTe devices were annealed in a H₂ atmosphere. This postprocessing treatment showed that J_{sc} increased to over 10 mA/cm². Study of CdZnTe solar cells is being carried out in various directions.

34.2.5 The Future of Cd-Based Solar Cells

From the development process of Cd-based solar cells, the study on the laboratory scale is being transferred to large-scale deposition and cell fabrication. Modules are being developed throughout the world, using the screen printing, evaporative deposition and close-space sublimation [34.31–33].

In order to make a commercial Cd-based photovoltaic cell with its full potential, a large-scale high-throughput manufacturing process is required. The process must possess excellent yields and produce high-efficiency devices with good long-term stability. In order to progress towards these goals, a pilot system for continuous, inline processing of CdS/CdTe devices has been developed [34.34–36]. High-quality low-cost thin-film CdTe modules with an average total area efficiency of 8% and cascaded production-line yield of > 70% have been manufactured, and technology-development programs will further increase production-line module efficiency to 13% within five years [34.36].

34.3 Radiation Detectors

A radiation detector is a device that converts a radiation ray into electrical signal. They can be divided into gas-filled detectors, scintillation detectors and

semiconductor detectors. Since semiconductor radiation detectors have a high spectrometric performance, and can be made portable, they have been applied

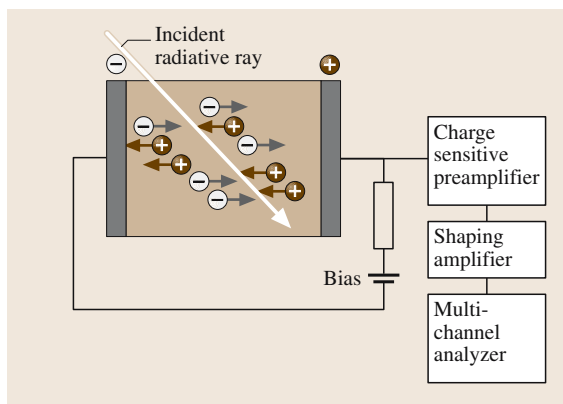

Fig. 34.7 The principle of operation of a semiconductor detector

in nuclear safeguards, medical physics and imaging diagnosis, industrial safety, nondestructive analysis, security and monitoring, nonproliferation and astrophysics [34.37, 38]. Meanwhile, they are also being gradually improved.

34.3.1 Basic Description of Semiconductor Radiation Detectors

The principle of operation of a semiconductor radiation detector is shown in Fig. 34.7. When high-energy photons (X- or γ -rays) radiate the detector, they lose the energy to induce electron–hole pairs in the semiconductor through photoelectric or Compton interactions, thereby increasing the conductivity of the material. In order to detect the change in conductivity, a bias voltage is required. An externally applied electric field separates the electron–hole pairs before they recombine, and electrons drift towards the anode, holes to the cathode. The charges are then collected by the electrodes. The collected charges produce a current pulse, whose integral equals the total charge generated by the incident photons, indicating the radiation intensity. The read-out goes through a charge-sensitive preamplifier, followed

by a shaping amplifier. The multichannel analyzer is used for spectroscopic measurements of the radiation ray. This type of detector can produce both count and energy information. Typically, detectors are manufactured in a square or rectangular configuration to maintain a uniform bias-current distribution throughout the active region. The wavelength of the peak response depends on the material's band-gap energy.

There are several important parameters to describe a detector performance. Detection efficiency is defined as the percentage of radiation incident on a detector system that is actually detected. Detector efficiency depends on the detector size and shape (larger areas and volumes are more sensitive), radiation type, material density (atomic number), and the depth of the detection medium. Energy resolution is one of the most important characteristics of semiconductor detectors. It is usually defined as the full-width at half-maximum (FWHM) of a single-energy peak at a specific energy. High resolution enables the system to more clearly resolve the peaks within a spectrum. So the reliability of the detector is also high. Detector sensitivity implies minimal detectable counts. It is defined as the number of counts that can be distinguished from the background. The relative detector response factor expresses the sensitivity of a detector relative to a standard substance. If the relative detector response factor is expressed on an equal-mass (-weight) basis, the determined sensitivity values can be substituted for the peak area.

34.3.2 CdTe and CdZnTe Radiation Detectors

Semiconductor radiation detectors are fabricated from a variety of materials including: germanium (Ge), silicon (Si), mercuric iodide (HgI_2), CdTe, CdZnTe etc.. Typical detectors for a given application depend on several factors. Table 34.2 shows the features of some semiconductor detectors. From Table 34.2, Ge detectors have the best resolution, but require liquid-nitrogen cooling, which makes them impractical for portable applications.

Table 34.2 The features of some semiconductor detectors

	NaI	Si	Ge	CdTe	$\text{Cd}_{0.9}\text{Zn}_{0.2}\text{Te}$
Bandgap (eV) at 300 K	–	1.14	0.67	1.54	1.58
Density (g/cm^3)	3.67	2.33	5.35	6.2	5.78
Energy per e–h pair (eV)	–	3.61	2.96	4.43	4.64
Detection/absorption	High	Low	Medium	High	High
Operation at room temp.	Yes	Yes	No	Yes	Yes
Spectrometric performance	Medium	High	Very high	High	High

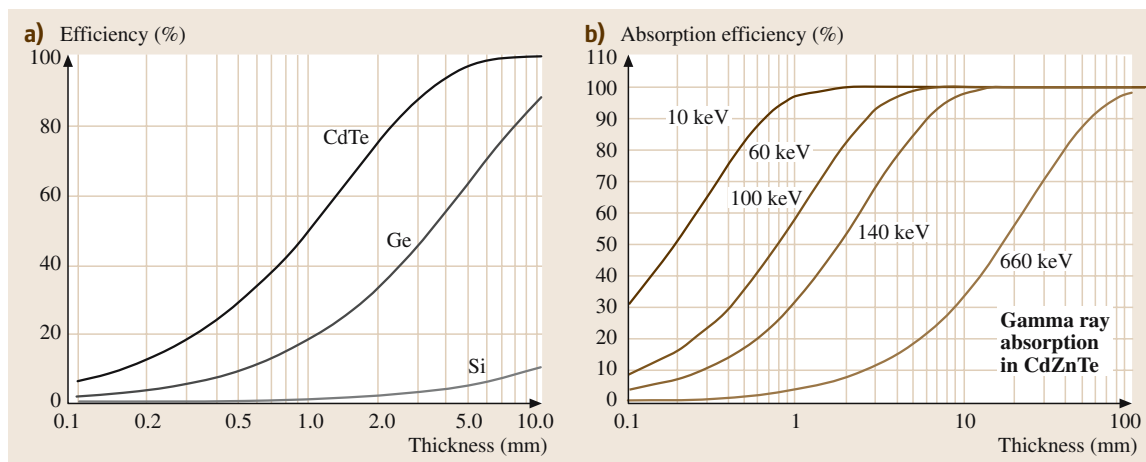

Fig. 34.8a,b γ -ray absorption in CdTe (a) and CdZnTe (b) detectors as a function of thickness

Si detectors also need cooling, and are inefficient in detecting photons with energies greater than a few tens of keV. CdTe and CdZnTe detectors possess their own advantages.

Single crystals of CdTe and CdZnTe are very important materials for the development of X- and γ -ray detectors. Currently Ge and Si detectors have to be used at liquid-nitrogen temperatures, and suffer from poor detection efficiency. Since the compound semiconductors CdTe and CdZnTe with high atomic number ($Z_{Cd} = 48$, $Z_{Zn} = 30$, $Z_{Te} = 52$) have a significantly higher photoelectric absorption efficiency in the -100–500 keV range, they can be fabricated into detectors that provide two advantages for use in portable instrumentation: (1) the large band-gap energy ($E_g > 1.54$ eV at room temperature) results in extremely small leakage current of a few nanoamps at room temperature. Therefore, these detectors have the potential to serve as useful detectors for radiation spectroscopy without the need for cryogenic cooling as required for more conventional silicon and hyper-pure germanium detectors; (2) the high density of the crystal provides excellent stopping power over a wide range of energies. The ability to operate at room temperature without the need for liquid-nitrogen cooling allows the construction of compact devices. CdTe and CdZnTe detectors can be fabricated into a variety of shapes and sizes, which makes it possible to produce detectors capable of meeting the requirements of a wide assortment of applications that are unsupported by other detector types. Their small size and relatively simple electronics allow them to open new areas of detector application. In many instances, CdTe and CdZnTe detectors

can be substituted for other detector types in existing applications.

Figure 34.8 shows the γ -ray absorption efficiency in: (a) CdTe, and (b) CdZnTe detectors as a function of thickness. It was reported that, for a detector with a thickness of about 10 mm detecting 100-keV γ -rays, the detection efficiency for a CdTe detector is 100%, for a Ge detector 88%, for a Si detector only 12% [34.39]. In the case of a CdZnTe detector, CdZnTe with a thickness of only about 7 mm can absorb 100% of the γ -rays [34.40]. This efficiency assumes that the γ -ray is completely absorbed and the generated electron-hole pairs are completely collected. In fact, a large amount of charge loss occurs in CdTe and CdZnTe detector, depending on the quality of the materials.

34.3.3 Performance of CdTe and CdZnTe Detectors

Although CdTe and CdZnTe have many advantages over Si and Ge, including higher attenuation coefficients and lower leakage currents due to the wider bandgap, their disadvantages limit their application range [34.41]. The main disadvantage is that their crystals usually contain higher density defects. These defects are remaining impurities and structural defects such as mechanical cracks, twins, grain and tilt boundaries, and dislocations all lower the crystalline perfection of the materials.

In CdTe and CdZnTe detectors, the charge transport determines the collection efficiency of generated electron-hole pairs, and structural properties of materials control the uniformity of the charge transport. The

problem of poor transport and collection of carriers, especially hole, can be overcome by applying high voltage to device and a range of electrode config. The former is related to high resistivity material, and later is related to the design of a detector. In addition, it was found that detected pulse signal intensity degraded with the time [34.42, 43]. This phenomenon was thought to be mainly related to the defects existing in bandgap. When the detector starts to work, these defects could act as slowly ionized acceptors. The low resistivity and poor quality material always exhibits such a polarization effect.

Summarizing above, improvement of a detector performance is equivalent to the improvement of the crystallinity of CdTe and CdZnTe. The key feature of all applications except substrate materials of CdTe and CdZnTe is the resistivity. This is because high resistivity can be obtained only by controlling native defects and impurity concentration. For many years, much effort was done in preparing high quality CdTe and CdZnTe single crystals.

Progresses in Crystal Growth of High Quality CdTe and CdZnTe

Various techniques have been applied to grow high-quality CdTe and CdZnTe single crystals. The Bridgman method [34.44, 45], the traveling-heater method [34.46, 47], growth from Te solvent [34.48], the gradient-freeze method [34.49, 50], and physical vapor transport [34.51, 52] are the most widely used. Crystals with applicable quality and size have become available, and have also fostered the rapid progress of research on CdTe.

As-grown CdTe single crystals commonly contain high concentration of both residual impurities and intrinsic defects. Preparation of high-purity high-resistivity CdTe and CdZnTe crystals has been widely attempted [34.53]. Early works was done by *Triboulet* and *Marfaing* [34.54] in obtaining high-purity lightly compensated zone-melting growth following synthesis by the Bridgman method. The room-temperature carrier concentrations range from 1 to $5 \times 10^{13} \text{ cm}^{-3}$, and the resistivity from 100 to $400 \Omega \text{ cm}$. The carrier mobility at 32 K reaches as high as $1.46 \times 10^5 \text{ cm}^2/\text{Vs}$. The total concentration of electrically active centers was estimated to be about 10^{14} cm^{-3} .

Usually, as-grown CdTe crystal shows p-type conductivity owing to the existence of remaining acceptor impurities or native defects. For this reason, many results have been reported in preparing high-resistivity CdTe. Chlorine (Cl) is thought to be a suitable donor for the compensation of these remaining acceptors because

Cl can be doped quite uniformly due to its very small segregation coefficient [34.55].

The growth of high-resistivity CdTe:Cl single crystals with device quality was successfully performed by the traveling-heater method (THM) [34.55]. Solvent alloys for THM growth were synthesized in ampoules filled with Te, CdTe and CdCl_2 so that the molar ratio of Te/Cd was the same as in the solvent zone during the growth. The Cl concentration in the grown crystal was 2 weight – ppm. According to the dynamics of the crystal growth, it is important to control the shape of the solid–liquid to grow high-quality single crystals. Therefore, the solvent volume was optimized. The use of a slightly tilted seed from $\langle 111 \rangle \text{B}$ was also effective in limiting the generation of twins with different directions. Single-crystal (111) wafers, larger than $30 \times 30 \text{ mm}^2$ were successfully obtained from a grown crystal with a diameter of 50 mm. Pt/CdTe/In detectors with dimensions of $2 \times 2 \times 0.5 \text{ mm}^3$ showed better energy resolution, because a higher electric field can be applied. The effective detector resistivity was estimated to be $10^{11} \Omega \text{ cm}$.

CdTe doped with chlorine (Cl) or indium (In) with a resistivity of $3 \times 10^9 \Omega \text{ cm}$ and CdZnTe with a resistivity of $5 \times 10^{10} \Omega \text{ cm}$ were grown by the high-pressure Bridgman (HPB) technique [34.56]. The material was polycrystalline with large grains and twins. Although the crystalline quality of HPB CdTe and CdZnTe is poor, the grains are large enough to obtain volume detectors of several cm^3 . Photoluminescence (PL) spectra at 4 K showed that the free exciton could be observed and the FWHM of the bound excitons is very low. Some impurity emissions were identified. The detectors were fabricated from HPB CdTe and CdZnTe. These detectors showed excellent performance. Gamma-ray spectra were presented with high-energy resolution in an energy range from 60 to 600 keV. Using a $10 \times 10 \times 2 \text{ mm}^2$ HPB detector, at a bias of 300 V, the peak at 122 keV from ^{57}Co had a FWHM of 5.2 KeV. Detectors with high-energy resolution were fabricated.

Because of the difference in vapor pressure between Cd and Te, grown crystals contain a large number of Cd vacancies (V_{Cd}). These Cd vacancies manifest acceptor behaviour. Therefore, high-resistivity CdTe can also be obtained by controlling the concentration of Cd vacancies. However, a prerequisite is that the purity of the CdTe crystal is high enough that the remaining impurities do not play a substantial role in determining the conductivity. Recently, the preparation of ultra-high-purity CdTe single crystals was reported [34.57, 58]. In order to obtain a high purity the starting mater-

Fig. 34.9 A typical high-resolution PL spectrum of a high-purity CdTe sample

ials of Cd and Te, Cd were first purified by vacuum distillation (VD) and the overlap zone-melting (OZM) method [34.57], while Te was purified using the normal freezing method [34.58]. The results of glow-discharge mass spectroscopy (GDMS) and the measurement of the residual resistivity ratio (RRR) showed that refined Cd and Te had the purity of 6N-up. Using the refined Cd and Te as starting materials, extremely high-purity twin-free CdTe single crystals were prepared by the traditional vertical Bridgman technique. Figure 34.9 shows a typical high-resolution PL spectrum of a high-purity CdTe sample. Only a sharp and strong emission line of (A^0, X) (an exciton bound to a neutral acceptor) at 1.5896 eV was observed. The FWHM of the (A^0, X) line is 0.31 meV. This is the narrowest value ever reported for CdTe single crystals grown by the Bridgman method. All of the above indicate that the sample is of high purity and quality. For a good performance detector, the leakage current must not exceed a few nanoamps, which requires a material with high resistivity. When growing CdTe crystals, the CdTe contain large number of Cd vacancies due to the extreme volatility of Cd. For these reason, CdTe single crystals were annealed in a Cd atmosphere in order to obtain a high-resistivity crystal. Hall-measurement results showed that the conductive type changed from as-grown p-type to n-type at a Cd pressure around 1.5×10^{-2} atm, corresponding to a Cd source temperature of 500 °C. Samples annealed under these conditions showed a resistivity as high as $10^9 \Omega\text{cm}$.

Lachish [34.59] grew CdTe and CdZnTe crystals with excess cadmium in order to avoid the Te precip-

itates found in crystals grown by Bridgman method. During crystal growth one ampoule end was kept at a low temperature, which determines a constant, nearly atmospheric, vapor pressure in the system. The constant vapor pressure maintains a constant liquid composition and balanced amounts of cadmium and tellurium within the crystal. Although the highly donor-doped crystals are highly electrically conducting, successive annealing in Te vapor transforms the crystal wafers into a highly compensated state showing high electrical resistivity and high gamma sensitivity, depending on the doping level.

Improvements of Transport and Collection of Carriers in CdTe and CdZnTe Detectors

The transport and collection of carriers in CdTe and CdZnTe, especially holes, are the main problems that affect their performance. Poor carriers transport causes position-dependent charge collection and limits their capability as high-resolution spectrometers [34.60]. As a result, this limits the volume of detector. Therefore, the efficient detecting resolution and range are decreased. Amman et al. [34.61] studied the affect of nonuniform electron trapping on the performance of a γ -ray detector. An analysis of the induced charge signals indicated that regions of enhanced electron trapping are associated with inclusions, and that these regions extend beyond the physical size of the inclusions. Such regions introduce nonuniform electron trapping in the material that then degrades the spectroscopic performance of the material as a γ -ray detector. The measurements showed that the degree of nonuniformity that affects detector performance could be at the 1% level. Consequently, any useful characterization and analysis technique must be sensitive down to this level.

Detectors equipped with Ohmic contacts, and a grounded guard ring around the positive contact, have a fast charge-collection time. Conductivity adjustment, in detectors insensitive to hole trapping, optimizes the detector operation by a trade-off between electron lifetime and electrical resistance. Better hole collection has been achieved by designing detectors and electrodes of various geometries. Nakazawa et al. [34.62] improved the CdTe diode detectors by fabricating the guard-ring structure in the cathode face, and the leakage current of the detector decreased by more than an order of magnitude. The new CdTe detector was operated with a bias as high as 800 V at 20 °C and showed a good energy resolution (0.93 keV and 1 keV FWHM for 59.5 keV and 122 keV, respectively) and high stability for long-term operation at room temperature. Furthermore, they also developed a large-area ($20 \times 20 \text{ mm}^2$) detector with

very high resolution. Owing to its high stopping power and high resolution at room temperature, pixel imagers have also been developed in the same group, and it is thought that this large diode detector could possibly be a substitute for scintillation detectors.

Since the carriers drift slow and have a short lifetime in CdTe detectors, the number of photons in the photo-peak is reduced and the spectrum is distorted by a tail towards lower energies. For these reasons, CdTe detectors are usually made into Schottky diodes, because this structure can withstand much higher bias voltage with a leakage current orders of magnitude lower than detectors with Ohmic contacts. *Takahashi et al.* [34.63] adopted the configuration of Schottky CdTe diode, which due to the low leaking current, makes it possible to apply a much higher bias voltage to ensure complete charge collection in relatively thin (< 1 mm) devices. Both the improved charge-collection efficiency and the low leakage current lead to an energy resolution of better than 600 eV FWHM at 60 keV for a 2×2 mm² device without any electronics for charge-loss correction. Meanwhile, they also fabricated large-area detectors with dimensions of 21.5×21.5 mm², with a thickness of 0.5 mm and an energy resolution of 2.8 keV. Stacked detectors can measure the energies as high as 300 keV. Furthermore, a large-array detector, consisting of 1024 individual CdTe diodes, was also made. Every detector had a dimension of 1.2×5.0 mm². The total area, including the spaces between the detector elements, is 44×44 mm². This array detector is expected to be used in next-generation Compton telescopes.

34.3.4 Applications of CdTe and CdZnTe Detectors

Owing to the convenience of the smaller collimator, better resolution and temperature stability, CdTe and CZT detectors have been used in safeguard applications by the International Atomic Energy Agency (IAEA) and some countries for over ten years [34.64, 65]. With the gradual improvement in performance, CdTe and CdZnTe detectors are replacing NaI detectors used in spent-fuel attribute tests [34.66], though their sensitivity is still low compared to NaI and Ge detectors, although already sufficient for many applications. CdTe detectors have a sensitive volume of about 20–100 mm³ and a probe diameter of 8–9 mm. CdZnTe detectors have a larger volume than CdTe detectors. The largest commercial CdZnTe detectors have a geometric volume of 1687 mm³ ($15 \times 15 \times 7.5$ mm³). Detectors are mainly of hemispheric design to obtain

high carrier-collection efficiency. These large-volume detectors have been made into portable and hand-held isotope-identification devices and are being used to detect radioactive sources. They will become commercially available in the near future.

At present, conventional X-ray film or scintillator mammograms are used in medical diagnostics such as screening for breast cancer. However, these show a non-linear response to X-ray intensity and the detection quantum efficiency is low. Room-temperature semiconductor detectors such as CdTe and CdZnTe have favorable physical characteristics for medical applications. From the start of these investigations in the 1980s, rapid progress has been achieved [34.67–72]. *Barber* [34.68] presented results concerning, first, a CdTe two-dimensional (2-D) imaging system (20×30 mm² with 400×600 pixels) for dental radiology and, second, a CdZnTe fast pulse-correction method applied to a $5 \times 5 \times 5$ mm³ CdZnTe detector (energy resolution of 5% for a detection efficiency of 85% at 122 keV) for medical imaging. After that, a 2-mm-thick CdZnTe detector was fabricated for application to digital mammography [34.70]. The preliminary images showed high spatial resolution and efficiency. Furthermore, CdTe and CdZnTe detectors with a thickness of 0.15–0.2 mm were fabricated [34.72]. The detectors are indium-bump-bonded onto a small version of a chip. Their detection quantum efficiency was measured as 65%. This result showed that CdTe and CdZnTe detectors are superior to scintillator-based digital systems, whose quantum efficiency is typically around 30–40%. This showed that CdTe and CdZnTe detectors have potential applications in medical imaging, as well as industrially for nondestructive evaluation inspection.

In universe exploration, Cd-based detectors can be used in an advanced Compton telescope (ACT) planned as the next-generation space-based instrument devoted to observations of low/medium-energy γ -rays (≈ 0.2 –30 MeV) and to the nonthermal energy exploration telescope (NeXT) [34.73]. In the universe, radiation rays have a wide energy range of 0.5–80 keV. In order to detect this wide range of radiation, *Takahashi et al.* [34.74–76] proposed a new focal-plane detector based on the idea of combining an X-ray charge-coupled device (CCD) and a CdTe pixel detector as the wide-band X-ray imager (WXI). The WXI consists of a soft-X-ray imager and a hard-X-ray imager. For the detection of soft X-rays (10–20 keV) with high positional resolution, a CCD with a very thin dead layer will be used. For hard X-rays, CdTe pixel detectors serve as absorbers. This study is now under way.

34.4 Conclusions

Devices fabricated from Cd-based compounds, such as solar cells and radiation detectors, are being applied in our daily life. In the case of solar cells, although recent success have improved their conversion efficiency and reduced the cost, many problems remain. Fundamental understanding of the CdTe-based solar-cell properties is limited, particularly as a result of their polycrystalline nature. Therefore, the fundamental electronic properties of polycrystalline Cd-based thin films should be studied deeply. Other challenges are to reduce the cost and to lengthen the operating life span. These problems are being studied and solved [34.77].

In the case of radiation detectors, CdTe and CdZnTe detectors have many advantages, such as room-temperature operation, high count rates, small size, and direct conversion of photons to charge, which make them attractive candidates for a wide variety of applications in industrial gauging and analysis, as well as medical instrumentation and other areas. These detectors are being made available commercially at present. However, they have severe problems such as polarization effects, long-term stability and their high price. Further efforts should still be focused on the preparation of high-quality materials and improvement of the stability and reliability of detectors. We are confident that radiation detectors made from

Cd-based compounds will achieve more widespread application.

Definition of Terms

- **Cd-based compound semiconductor:** a semiconductor that contains the element Cd.
- **Heterojunction:** a junction between semiconductors that differ in their doping-level conductivities, and also in their atomic or alloy composition.
- **Band gap:** energy difference between the conduction band and the valence band.
- **n-type conductivity:** a semiconductor material, with electrons as the majority charge carriers, that is formed by doping with donor atoms.
- **p-type conductivity:** a semiconductor material in which the dopants create holes as the majority charge carrier, formed by doping with acceptor atoms.
- **Solar cell:** a semiconductor device that converts the energy of sunlight into electric energy. Also called a photovoltaic cell.
- **Semiconductor detector:** a device that converts the incident photons directly into an electrical pulse.
- **Conversion efficiency:** the ratio of incident photon energy and output electricity energy.
- **Detection efficiency:** percentage of radiation incident on a detector system that is actually detected.

35. Doping Aspects of Zn-Based Wide-Band-Gap Semiconductors

The present Chapter deals with the wide-band-gap (defined here as greater than 2 eV) Zn chalcogenides, i. e. ZnSe, ZnS, and ZnO (mainly in bulk form). However, since recent literature on ZnS is minimal, the main coverage is of ZnSe and ZnO. In addition $\text{Zn}_{1-x}\text{Be}_x\text{Se}$ ($x \leq 0.5$) is included, since Be is expected to reduce degradation (from light irradiation/emission) in ZnSe. The main emphasis for all these materials is on doping, in particular p-type doping, which has been a problem in all cases. In addition, the origin of light emission

35.1	ZnSe	843

35.3	ZnO	849
35.3.1	Doping	849
35.3.2	Optical Properties	850
	References	851

in ZnO is not yet well established, so this aspect is also briefly covered.

The present Chapter treats the wide-band-gap (defined here as greater than 2 eV) Zn chalcogenides (as well as ZnBeSe), i. e., ZnSe, ZnS, and ZnO, with room-temperature band gaps of 2.7 eV, 3.7 eV, and 3.4 eV, respectively. We shall here concentrate mainly on bulk properties, since quantum dots and quantum wells are treated elsewhere in this Handbook except when these (or other nanostructures) are involved in bulk doping (Sect. 35.1.2). The primary emphasis will be on literature from 2000 to 2004. Moreover, since there have been few publications on ZnS in the last four years (our literature search showed only seven publications) [35.1–7], the present review will effectively cover ZnSe, ZnBeSe, and ZnO.

It is well known that the primary interest in these materials is their ability to provide light emission and/or detection in the green and higher spectral ranges. One of the major problems for these materials is obtaining good bipolar doping, in particular good p-type doping

for ZnO, ZnSe, and ZnBeSe with low fractions of Be; this problem has for instance been reviewed for ZnO by Pearton et al. [35.8] and by Look and Claflin [35.9] and for ZnSe by Neumark [35.10]. A second problem, especially for ZnSe-based devices, is that of degradation under photon irradiation, including those generated during light emission [35.11–14]. It is for this reason that ZnBeSe is of high interest, since Be is expected to *harden* ZnSe, i. e. to reduce defect formation and thus degradation [35.15–17].

ZnO is one of the most studied materials in the group of II–VI semiconductors because of its wide band gap (3.36 eV at room temperature) and its bulk exciton-binding energy (60 meV), which is larger than the room-temperature thermal energy. In addition to room-temperature ultraviolet (UV) optoelectronic devices, it can be used for magnetic [35.18] and biomedical applications [35.19] and references therein.

35.1 ZnSe

35.1.1 Doping – Overview

Despite many years of effort, p-type doping of ZnSe is still a problem. The main success to date has been achieved with nitrogen as the primary dopant. Of other dopants, Li diffuses extremely fast [35.20] and also self-compensates via interstitial Li [35.20, 21], Na has a predicted maximum equilibrium solubility of

$5 \times 10^{17} \text{ cm}^{-3}$ [35.22] and also self-compensates (via interstitial Na), as shown by Neumark et al. [35.23], P and As give DX centers and thus give deep levels (as summarized for instance by Neumark [35.10]), and Sb to date has given net acceptor concentrations of only about 10^{16} cm^{-3} (see Table 35.1). Regarding, N doping, Table 35.2 lists recent results on concentrations of holes (p) or net acceptors ($[n_a - n_d]$), where n_a (n_d) is the accep-

Cl			The PL is dominated by the Cl ⁰ X line at 2.797 eV (10 K). Above 200 K, the intensity of the Cl ⁰ X line decreases rapidly due to the presence of a nonradiative center with a thermal activation energy of ≈ 90 meV. The decrease of the Cl ⁰ X line over the temperature range 10–200 K is due to the thermal activation of the Cl ⁰ X line bound exciton to a free exciton with abactivation energy of ≈ 9.0 meV	[35.37]
Cl		MBE	At high ZnCl ₂ beam intensity, crystallinity deteriorates due to excess Cl atom	[35.38]
Cl		MBE	At low T, the dominate PL is due to neutral donor-bound excitons; at high T, the dominate PL is due to free-to-bound recombination. At low T, two additional lines on the high-energy side are observed (light- and heavy-hole free-exciton transitions); one additional peak at the low-energy side (DAP ^a transition)	[35.39]

tor (donor) concentration, in various approaches, where these are greater than 10^{18} cm^{-3} . We note in connection with Table 35.2 that degradation associated with N can be a severe problem [35.11, 12], and we also give some comments on degradation in the table. We shall discuss two N-doped systems in more detail below Sect. 35.1.2. One uses delta-doping with Te as co-dopant (for this system, a material used to help in incorporating the dopant); this system has given net acceptor concentrations up to $6 \times 10^{18} \text{ cm}^{-3}$ [35.24] with very low Te concentrations, so that minimal degradation is expected. The second system is that of Li_3N doping, with a report of carrier concentrations close to 10^{19} cm^{-3} . We list recent work on p-type dopants other than N in Table 35.1.

Interestingly, there are two reports that Sb gives quite low activation energies, one being 69 meV [35.25] and the other being 55 meV [35.27] (note that the activation energy for N is 111 meV [35.48]), with the former paper giving a net acceptor concentration of about 10^{16} cm^{-3} ; in this connection it should still be noted that, as mentioned, As and P are generally believed to form DX centers and give deep levels (for a summary [35.10]). Other dopants used were K and Na, with doping carried out via excimer laser annealing; high doping levels were reported, but the excimer procedure would be expected to introduce high defect densities and resultant strong degradation (note that the maximum equilibrium solubility for Na was predicted to be about $5 \times 10^{17} \text{ cm}^{-3}$ by Van de Walle et al. [35.22]). A further approach was that of co-doping, where the term in this case means incorporation of both donors and acceptors; here, experimental tests were reported for Li with I in one case, and with Cl in another, but in both cases net acceptor concentrations were only in the 10^{16} cm^{-3} range. An additional method was to use planes of p-type GaAs (doped with Zn) to inject holes into ZnSe; net acceptor concentrations of 10^{17} cm^{-3} were reported in [35.32], where metalorganic molecular beam epitaxy (MOMBE) was used.

For completeness, we also list in Table 35.3 recent results on n-type doping.

35.1.2 Results on p-Type Material with N as the Primary Dopant

Recent methods for p-type doping with p or $[n_a - n_d]$ exceeding 10^{18} cm^{-3} have been listed in Table 35.2. Note that all of these use N as the primary dopant. As additional comments we note that growth by metalorganic vapor-phase epitaxy (MOVPE) is now relatively standard, and that a quite comprehensive discussion of this method has recently been given [35.49] (although it must be noted that the “hole concentration” of $3 \times 10^{18} \text{ cm}^{-3}$, given in Table 1 of Prete et al. [35.49] from data given in Fujita et al. [35.50], is in fact the N concentration, with Fujita et al. [35.50] giving p as $8 \times 10^{17} \text{ cm}^{-3}$); in view of this extensive recent paper, we do not discuss MOVPE here, but merely give in Table 35.4 some recent references (not in [35.49]). We further note that the use of a δ -ZnSe/ZnTe superlattice (SL) resulted in average Te concentrations of around 9%, which in turn increases the lattice mismatch between the GaAs substrate and the film, since the ZnTe lattice constant is larger than that of ZnSe. This is expected to lead to degradation problems [35.36].

A novel, interesting approach, which has given net acceptor concentrations up to $6 \times 10^{18} \text{ cm}^{-3}$, is that of incorporating both N as a dopant and Te as a co-dopant into the δ -layer(s) with fractional ZnTe coverage, via molecular-beam epitaxy (MBE) [35.24]; as previously mentioned (Sect. 35.1.1), co-dopant here means a material which aids in the incorporation of the dopant, and it is well known that it is easy to obtain p-type ZnTe [35.51, 52]. Electrochemical capacitance–voltage (E–CV) profiling results for various samples are shown in Fig. 35.1 (Fig. 3 of [35.24]); it can be seen that good doping was obtained when three contiguous layers of N and Te were incor-

porated (δ^3 -doped). A very important aspect of this system, established by subsequent work [35.33], is that the N is preferentially located within ZnTe, which was shown conclusively [35.33] to be present in submonolayer quantities, without formation of a standard SL (considering a standard SL to require full monolayers). This result was established by transmission electron microscopy (TEM), secondary-ion emission spectroscopy (SIMS), and high-resolution X-ray diffraction (HRXRD). SIMS data were taken on a specially prepared sample, in which the spacer regions (undoped ZnSe separating the δ -layers) were thick enough (in view of the SIMS resolution) that the SIMS measurements effectively gave the N and Te concentrations in the delta region. The results for a triple-doped sample are shown in Fig. 35.2, with a Te concentration of about $5 \times 10^{20} \text{ cm}^{-3}$ and an N concentration of about $5 \times 10^{19} \text{ cm}^{-3}$ for a “standard” 5 s Te + N deposition

Fig. 35.2 SIMS results on a δ^3 -doped ZnSe:(Te, N) sample. The upper line represents the [Te] concentration, and the lower line represents the [N] concentration

time [35.24]. Thus, both are present at far less than monolayer quantities.

Results from HRXRD are shown in Fig. 35.3, which gives (004) $\theta - 2\theta$ (solid black line) of a triple delta ZnSe:(Te,N) sample; this sample was grown in the [001] direction with a 10 nm ZnSe buffer layer, spacers of 10 monolayer (ML, where we here assume 1 ML, in the [001] growth direction, to be half of the lattice constant), and 200 spacer/ δ -region periods and was grown using a standard Te deposition time of 5 s [35.24]. The strongest peak, at $2\theta \approx 66.01^\circ$, is from the GaAs substrate. In addition, satellite peaks associated with the periodic structure along the growth direction are observed. The result of a simulation using dynamical diffraction theory [35.53–55] is shown by the dashed line. This fit is obtained with a δ -layer and spacer thicknesses of 0.25 ML and 10.4 ML, respectively. These values are in excellent agreement with the nominal growth conditions. The average Te concentrations are $\approx 37\%$ and 2.2% in the δ -layers and the spacers, respectively. The low average Te coverage and its relatively high concentration within the δ^3 -layers indicate that Te is not uniformly distributed within these layers, and, thus, forms ZnTe-rich nano-islands (such nano-islands have been observed by Gu et al. [35.56], optically, in similar samples grown without nitrogen). The relatively

Fig. 35.3 Symmetric $\theta-2\theta$ scan of a δ^3 -doped ZnSe: (Te,N). The solid black line is the experimental result, and the dashed line is the result of simulation. For clarity, the curves are shifted vertically

high Te concentration in the δ -layers is consistent with doping results obtained for ZnSeTe alloys, where it was shown that high acceptor concentrations are observed only for Te concentrations exceeding 15% [35.57]. A further important result for understanding the doping mechanism in the present system was that the photoluminescence (PL) quenched, with increasing temperature, with quite a low activation energy [35.33]; results are shown in Table 35.5, where it can be seen that the activation energies are far lower than for N in ZnSe (111 meV [35.48]) and decrease with increasing Te concentration, down to 38 meV, which is within the range 30–65 meV reported for ZnTe [35.36,58]. Thus, the N is associated primarily with ZnTe, i. e., the N is embedded primarily in Te-rich regions. It can also be noted from the SIMS results (Fig. 35.2) that N and Te are located in the same spatial region, and this is of course totally consistent with the view that N is embedded in Te-rich nano-islands.

We next consider the case of doping by diffusion of Li_3N into MOVPE-grown material [35.34]. The view

has been expressed [35.59] that the resultant good doping was due to the incorporation of Li into Zn sites, and N into Se sites, with both such species being acceptors. In our view, this conjecture is unlikely. Thus, we note that in hard-to-dope wide-band-gap materials, strong compensation is expected [35.60]; since interstitial Li is a donor, it seems very likely that considerable Li is incorporated into the interstitial site after diffusion. Moreover, it is known [35.20] that Li diffuses very quickly. Thus we suggest that, during contact formation, even with minimal heating, a good fraction of the interstitial Li diffuses into precipitates, leaving the material p-type. We note that this view is reinforced by the work of Strassburg et al. [35.61], who show that this method works very well if doping is carried out by ion implantation; such implantation is expected to cause a high density of lattice defects, where defects would be expected to act as nucleation sites for precipitation of interstitial Li.

Last, but not least, no discussion of N doping would be complete without pointing out that it is now realized that N, to a greater or lesser extent (depending on conditions), does self-compensate, i. e. it does introduce donors. The nature of the donors will depend on the Fermi level and on the Zn (Se) and N chemical potentials, as shown in theoretical analyses by Van de Walle et al. [35.22], Kwak et al. [35.62] and Cheong et al. [35.63]. A discussion and comparison of these papers, as well as of the minimum requirements for reliable first-principles calculations, has been given by Neumark [35.10]. Additional work by Faschinger et al. [35.64] and Gundel and Faschinger [35.65] suggested, based on first-principles calculations, a complex between interstitial N (N_i) and a Se vacancy (V_{Se}), but no dependence on the Fermi level or chemical potentials was given.

Moreover, experimentally, Kuskovsky et al. [35.66] have reported a double N interstitial donor at high N doping, and Desgardin et al. [35.67] have reported a $[\text{V}_{\text{Se}}\text{N}_{\text{Se}}]$ complex and a V_{Zn} point defect. Furthermore, it has also been shown that the N_i species (and probably complexes) contribute to degradation [35.11,12,68], but details of this process do not yet appear well understood, and we thus merely mention its existence. However,

Table 35.5 Sample parameters and photoluminescence properties of δ^3 (Te, N)-doped ZnSe

Te concentration (%)	$n_a - n_d$ (cm^{-3})	PL quenching activation energy (meV)
< 3	6.0×10^{18}	38
1.3	4.0×10^{18}	72
< 1	3.0×10^{18}	87

a point we do want to emphasize in this regard is that it might be highly advantageous to be able to use a dopant other than N. We thus note that, with the approach of Lin et al. [35.24], one can envision the use of a dopant

other than N, since the acceptors are not located within ZnSe, but rather in a favorable ZnTe-rich environment. We thus point out that P and As are excellent p-dopants in ZnTe [35.69, 70].

35.2 ZnBeSe

As mentioned in Sect. 35.1, the best p-type dopant developed to date for ZnSe is nitrogen, and such N-doped material suffers from degradation problems. To alleviate this problem, the use of ZnBeSe has been suggested [35.15, 16]. BeSe is *harder* than ZnSe (Fig. 35.4 [35.71]) and, since it is expected that harder materials are less susceptible to defect formation (dislocations etc.), it is expected to be less susceptible to degradation [35.15, 16]. It has been shown that the hardness of ZnBeSe increases with increasing Be content, at least up to 60% Be, as shown in Fig. 35.4 [35.71], where it should be noted that the experimental error at the higher Be concentrations is quite large (moreover, the main interest in ZnBeSe is in the direct-band range, i.e. below 46% [35.72]).

Fig. 35.4 Variation of elastic modulus E as a function of alloy composition x in $\text{ZnBe}_x\text{Se}_{1-x}$. The data points represent the average value. The *squares* – joined by the *full line* – show results obtained under peak loads of 1 mN for alloys grown onto GaAs. *Crosses* are for data obtained under 10 mN for alloys grown onto GaAs and *open circles* show data obtained under 1 mN for alloys grown onto GaP. We note that in general Young's modulus is related to material hardness [35.17]. After [35.71]

It can be pointed out that two additional advantages of ZnBeSe over ZnSe are that one can adjust the lattice constant for better lattice-matching to various materials of interest (GaAs – the most frequently used substrate), and that one can obtain a wider band gap. For instance, $\text{Zn}_{0.028}\text{Be}_{0.972}\text{Se}$ is lattice-matched to GaAs [35.73] and $\text{Zn}_{0.55}\text{Be}_{0.45}\text{Se}$ [35.74] is lattice-matched to Si (assuming a BeSe lattice constant of $\approx 5.138 \text{ \AA}$). The variation of the band gap has been studied in a number of recent papers [35.72, 75]. One result, over the entire concentration range, is shown in Fig. 35.5 [35.72]. It can be seen that the band gap becomes indirect for Be concentrations above 46%; thus, very high Be concentrations are not as interesting, since they cannot be used to give diode lasers.

Fig. 35.5 Evolution of the direct band gap (\circ) and of the main PL peak (\blacksquare) as a function of the Be content in $\text{Zn}_{1-x}\text{Be}_x\text{Se}$ alloys. After [35.72]

Table 35.6 XRD, EPD, and C–V results for undoped, N-doped, and (N + Te) δ -doped ZnBeSe epilayers [35.76]

	ZnBeSe	ZnBeSe : N	ZnBeSe : (N + Te) δ	ZnBeSe : (N + Te) δ^3
FWHM (arcs)	23	30	45	51
Be content (%)	3.1	2.6	2.6	2.5
Te content (%)	0	0	0.3	0.5
EPD (cm^{-2})	4×10^4	1×10^5	6×10^5	5×10^5
$n_a - n_d$ (cm^{-3})	–	2×10^{17}	3×10^{17}	1.5×10^{18}

A problem for ZnBeSe, as for ZnSe, is that of p-type doping. The highest bulk net acceptor concentration in p-type ZnBeSe does not exceed $\approx 2 \times 10^{17} \text{ cm}^{-3}$ [35.76]. The best p-type results were again obtained via delta-

doping [35.76], using the same method that Lin et al. [35.24] used for ZnSe. The results from Guo et al. [35.76] are shown in Table 35.6 (Table I from [35.76]).

35.3 ZnO

ZnO is a wide-band-gap (3.36 eV at room temperature) semiconductor with a bulk exciton-binding energy (60 meV), larger than the room-temperature thermal energy, which makes this material very suitable for a variety of applications (see recent reviews by Pearton et al. [35.18], Heo et al. [35.87] and Djurišić et al. [35.88]) in the UV spectral range. However, as for ZnSe and ZnBeSe, one of the major problems for ZnO is p-type doping, and we shall therefore emphasize this aspect.

35.3.1 Doping

ZnO can be grown by a wide range of techniques (some of which are listed in Table 35.7). As-grown ZnO is usually n-type, and heavily n-type ZnO is easily obtained by using group III elements. It is assumed that nominally undoped ZnO is n-type due to shallow native defects such as interstitial zinc (Zn_i) [35.89, 90] or, alternatively, due to the presence of hydrogen [35.91]. Experimentally, hydrogen in ZnO has been observed

Table 35.7 p-type doping of ZnO

Dopant	Growth method	Resistivity (Ωcm)	Dopant concentration (cm^{-3})	Carrier concentration (cm^{-3})	Mobility (cm^2/Vs)	Reference
As	Evaporation followed by sputtering	0.4	Mid 10^{19}	4×10^{18}	4	[35.77]
As	Hybrid beam deposition	2	3×10^{18}	4×10^{17}	35	[35.78]

via electron paramagnetic resonance (EPR), electron nuclear double resonance (ENDOR), optical, and IR absorption measurements [35.92–95]. The activation energy of the hydrogen donor is 35–46 meV [35.92, 96]. We note that sometimes oxygen vacancies (V_O) are cited as shallow donors [35.97]; however, *Zhang et al.* [35.90] estimated this species to be a relatively deep level. Also, *Vanheusden et al.* [35.98, 99] suggested that charged oxygen vacancies are responsible for the deep green luminescence in ZnO (see below).

Obtaining good p-type ZnO has however proven difficult. There is a good discussion and summary of growth methods as well as achieved resistivities in p-type ZnO up to 2003 in *Look and Claffin* [35.9] and *Look et al.* [35.102]. The latter publication also discusses background impurities in ZnO. We therefore present only some later results and give a short discussion of models proposed for p-type doping of ZnO.

Group V acceptors, based on theoretical arguments, are expected to form very deep substitutional acceptors; for instance, *Park et al.* [35.103] have calculated that the ionization energies of N, P, and As are 0.40 eV, 0.93 eV, and 1.15 eV, respectively. So successes (Table 35.7) in obtaining p-type ZnO with N, P, and As are surprising. Also group I (Li, Na, and K) impurities [35.103] have, in general, lower ionization energies, but these impurities are amphoteric and thus self-compensate. Experimentally, interstitial Li and Na donors were observed by *Orlinskii et al.* [35.104], and recent attempt to use Li_3N to dope ZnO to be p-type produced n-type conductivity instead [35.105].

To achieve p-type doping, *Wang and Zunger* [35.106] have proposed a cluster co-doping method using Ga or Al as co-dopants along with group V dopants; experimentally, p-type ZnO has been obtained using co-doping with Al and In (Table 35.7); N–Ga co-doping has been attempted [35.107] but no p-type conductivity has been observed via the Hall effect.

Recently, to explain p-type ZnO obtained via group V doping, *Limpijumnong et al.* [35.108] proposed, using first-principles calculations, that group V elements give shallow acceptors by forming complexes with native defects. Specifically, these authors proposed that $ZnO:As$ and $ZnO:Sb$ are p-type due to $As_{Zn}-2V_{Zn}$ and $Sb_{Zn}-2V_{Zn}$ complexes, which behave as shallow acceptors. These complexes have low formation energies (1.59 eV and 2.00 eV, respectively) as well as low ionization energies (0.15 eV and 0.16 eV, respectively). Experimentally, the activation energy for $ZnO:As$ was reported to be between 0.12 [35.78] and 0.18 [35.109]. As for nitrogen, the most often used p-type dopant,

Look et al. [35.77] reported that the ionization energy was as low as 0.090 eV for heavily doped material (see also [35.110] and references therein).

Regarding doping using phosphorous, we note that *Kim et al.* [35.79] obtained p-type ZnO only after annealing at high temperatures using rapid thermal annealing (RTA), while as-grown material was n-type. The authors suggested that the annealing removes the compensating donors; however, we suggest that the formation of shallow acceptor complexes cannot be ruled out, especially in view of enhanced n-type behavior with increased P concentration [35.87].

Finally, we note that *Lee and Chang* [35.111] have proposed, theoretically, ways to use [group I – Hydrogen] complexes for p-type doping. These authors have found that an intentional co-doping with H impurities suppresses the formation of compensating interstitials and greatly enhances the solubility of Li and Na acceptors. This type of effect, in general, was clearly predicted by *Neumark* [35.112]. H atoms can be easily removed from ZnO by post-growth annealing at relatively low temperatures. Apparently, this method is similar to that used to obtain p-type GaN. These authors [35.111] also found, as did *Park et al.* [35.103], that Li and Na have lower ionization energies than substitutional group V dopants such as nitrogen.

35.3.2 Optical Properties

Finally, we shall briefly discuss some optical properties of ZnO. Low-temperature PL of undoped ZnO is dominated by near-band, edge emission, with up to 20 lines observed within the spectral range 3.34–3.38 eV [35.96]. Detailed studies of bound excitons (BX) and donor–acceptor pair luminescence have recently been published by *Meyer et al.* [35.96], so here

Table 35.8 Low-temperature bound-excitonic position and assignments

BX line energy (eV)	Assignment	Donor binding energy (meV)	References
≈ 3.3567	In	63.2	[35.96, 100]
≈ 3.3598	Ga	54.6	[35.96, 101]
≈ 3.3628	H	37 35 46.1	[35.92] [35.95] [35.96]
≈ 3.3608	Al	54.8 51.55	[35.96] [35.100]

we merely summarize some of their results and compare these with other reports.

An important conclusion was that all bound-excitonic lines are due to neutral donor-bound excitons, rather than, as previously suggested, to acceptor-bound excitons [35.113–115]. For instance, the ≈ 3.357 eV and ≈ 3.3608 lines are attributed to In and Al donors, respectively [35.113–115]. Similar conclusions were obtained by *Morhain* et al. [35.100] using PL and selective PL (SPL) on MBE-grown ZnO. It must be noted that such assignments were previously proposed by *Block* et al. [35.116] and *Gonzalez* et al. [35.117]. In Table 35.8 we summarize the BX lines that have been identified with a specific impurity or center. A line at 3.3631 eV, which is slightly above the 3.3628 eV line, was also assigned to hydrogen by *Look* et al. [35.95] who performed Hall-effect, PL, and EPR measurements on a series of ZnO samples annealed in air at various temperatures. The dominant donor had an activation energy of ≈ 37 meV, but disappeared after high-temperature annealing, and was replaced by a 67 meV donor [35.95]. The line at ≈ 3.3631 eV has been assigned to the 37 meV donor; the authors suggested, following *Hofmann* et al. [35.92], that this donor is hydrogen. This assignment has been confirmed by *Meyer* et al. [35.96] by SPL and by *Morhain* et al. [35.100] by magneto-optics, with *Meyer* et al. [35.96] reporting an H ionization energy of ≈ 46.1 meV.

Another important feature of bulk ZnO is a visible luminescence, often referred to as the green band. It is

usually observed at (2.38 ± 0.04) eV [35.118–121]. The origin of this band, however, remains controversial: transitions associated with O_{Zn} antisites [35.119], oxygen vacancies [35.97–99, 122], zinc interstitials [35.123], ZnO antisites [35.124], donor–acceptor pairs [35.125], and Cu^{2+} ions [35.126] have all been suggested. It must be noted that the origin of the green luminescence could be different in ZnO prepared via different methods, since various defects and/or impurities can contribute to the emission [35.127]. We note that oxygen vacancies are the species most often suggested as the defect associated with the green luminescence. Oxygen vacancies can have three states – neutral, singly and doubly positively charged. The transition thus depends on the type of free carrier that is participating in recombination. *Vanheusden* et al. [35.98, 99] suggested that holes participate in this recombination while *Djurišić* et al. [35.88] (also references therein) suggested the involvement of electrons. We have recently shown that the green luminescence most likely involves holes rather than electrons [35.128], via studies of quantum ZnO wires. A similar conclusion was also recently obtained by *Kang* et al. [35.129] who investigated PLD-grown ZnO. Their conclusion was that the most likely channel for the green PL is through a deep donor (attributed to oxygen vacancies) and the holes in the valence bands. Lastly, a further suggestion by *Harada* and *Hashimoto* [35.130] is that surface states associated with oxygen vacancies could play a significant role in the emission within the visible spectral region in bulk ZnO.

36. II–VI Narrow-Bandgap Semiconductors for Optoelectronics

The field of narrow-gap II–VI materials is dominated by the compound semiconductor mercury cadmium telluride, ($\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ or MCT), which supports a large industry in infrared detectors, cameras and infrared systems. It is probably true to say that HgCdTe is the third most studied semiconductor after silicon and gallium arsenide. $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ is the material most widely used in high-performance infrared detectors at present. By changing the composition x the spectral response of the detector can be made to cover the range from $1\text{ }\mu\text{m}$ to beyond $17\text{ }\mu\text{m}$. The advantages of this system arise from a number of features, notably: close lattice matching, high optical absorption coefficient, low carrier generation rate, high electron mobility and readily available doping techniques. These advantages mean that very sensitive infrared detectors can be produced at relatively high operating temperatures. $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ multilayers can be readily grown in vapor-phase epitaxial processes. This provides the device engineer with complex doping and composition profiles that can be used to further enhance the electro-optic performance, leading to low-cost, large-area detectors in the future. The main purpose of this chapter is to describe the applications, device physics and technology of II–VI narrow-bandgap devices, focusing on HgCdTe but also including $\text{Hg}_{1-x}\text{Mn}_x\text{Te}$ and $\text{Hg}_{1-x}\text{Zn}_x\text{Te}$. It concludes with a review of the research and development programs into third-generation infrared detector technology (so-called GEN III detectors) being performed in centers around the world.

The main commercial application for narrow-bandgap semiconductors is in infrared radiation detection. There are very few elemental or compound semiconductors

with the correct energy gap to sense photons within the infrared spectrum, particularly at longer wavelengths. It is also beneficial to accurately match the spectral sen-

sitivity to certain atmospheric windows, so the ability to tailor the wavelength is very important. By using an alloy of two different compounds with widely separate energy gaps it is possible to synthesize crystals with an intermediate energy gap. II–VI compounds have crystal properties that make them very suitable for mixing and they have a range of bandgaps from near zero for the semimetal Hg compounds to more than 1 eV.

However, amongst the wider bandgap II–VI semiconductors, only Cd, Zn, Mn and Mg have been shown to open up the bandgap of the Hg-based semimetals HgTe and HgSe. By far the most developed alloy system is $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ (HgCdTe), which is a semiconductor formed from the semimetal HgTe and the wide-bandgap semiconductor CdTe. By adjusting the alloy composition “ x ”, the properties (including the bandgap) can be varied smoothly between HgTe and CdTe.

There has been some interest in developing alternative ternary alloys to replace HgCdTe, since from theoretical considerations the already weak Hg–Te lattice bond is further destabilized by alloying with CdTe and there is potential for obtaining materials with increased hardness and detectors with better temperature stability. Most other compound combinations have crystal growth problems or doping limitations that make them unsuitable for device fabrication, with the possible exception of $\text{Hg}_{1-x}\text{Mn}_x\text{Te}$ and $\text{Hg}_{1-x}\text{Zn}_x\text{Te}$. Photoconductive detectors have been reported using $\text{Hg}_{1-x}\text{Mn}_x\text{Te}$, and photovoltaic detectors using both materials, but devices have not reached the maturity of $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$. Also, the technology reported for these materials is very similar to that of HgCdTe, and so many of the detector design, technology and performance factors described in this chapter for HgCdTe are also relevant to other II–VI alloys.

The main purpose of this chapter is to describe the applications, device physics and technology of II–VI narrow-bandgap devices, focusing on HgCdTe. It concludes with a review of the research and development programs into third-generation infrared detector technology (so-called GEN III detectors) being performed in centers around the world.

36.0.1 Historical Perspective and Early Detectors

Passive thermal imaging is the term used to describe imaging of the natural thermal radiation emitted by all objects around us. The contrast in such images is due to temperature differences and changes in emissivity or spectral radiance of surfaces. The atmosphere

is rather inconvenient for infrared imaging and is only transparent in certain wavelength “windows”. There is a short-waveband (SW) window between 2.0 and 2.25 μm , a medium-waveband (MW) window between 3.0 and 5.0 μm and a long-waveband (LW) window between 7.5 and 14 μm . The spectral radiance curve for bodies around room temperature shows a peak that best matches the LW window and this is the preferred wavelength of operation for thermal imaging detectors. At first sight the MW window looks compromised by the photon flux, which is some two orders lower than the LW window. However, it is much easier to make detectors for this wavelength, and the photon flux disadvantage can be offset by using staring architectures that enable a longer integration (or stare) time, and so this band is very widely used. The SW window is rarely used for passive thermal imaging because of low flux, but active imaging using a source such as starlight or an infrared laser is of growing interest.

The first infrared photon detectors, based on thallous sulfide, were developed in the USA during World War I and were sensitive to about 1.4 μm . The next important developments occurred before and during World War II in Germany, with work on thin-film polycrystalline PbS devices with a response up to 2.5 μm , later extended further to the 3–5 μm region using PbSe and PbTe. During the 1950s and 1960s indium antimonide (InSb) detectors emerged that were capable of detecting wavelengths up to 5.5 μm , and during the same period impurity photoconductivity was studied in doped germanium and doped silicon. Germanium was favored at this time because it was available with fewer compensating impurities and gave better detector performance. Ge : Hg, with an impurity activation energy of 0.09 eV, provided the first practical detector to be used in real-time thermal imaging, employing linear arrays for the 8–13 μm region, although it required cooling to below 30 K. Because of the stringent cooling requirements, extrinsic silicon devices have not found favor for terrestrial applications.

The next important phase of semiconductor infrared detector research took place during the late 1960s and 1970s, when research efforts were directed towards an intrinsic detector for the 8–13 μm band that would operate more conveniently at around 80 K. Two alloy semiconductors were developed, $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ (HgCdTe) and $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ (LTT). The first report of the synthesis of the semimetal HgTe and the wide-bandgap semiconductor CdTe to form the semiconductor alloy HgCdTe was published by the Royal Radar Establishment in Malvern, UK [36.1]. This landmark paper

reported both photoconductive as well as photovoltaic response at wavelengths extending out to $12\text{ }\mu\text{m}$, and pointed out that this new alloy semiconductor showed promise for intrinsic infrared detectors. Soon after many centers around the world switched detector development for major thermal-imaging programs to the HgCdTe system. High-performance LW and MW linear arrays were produced for the first generation of thermal imaging equipment developed and manufactured in the 1970s through to the present. Many tens of thousands of detectors have been delivered.

36.0.2 Introduction to HgCdTe

$\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ is the material most widely used for high-performance infrared detectors at present. By changing the composition x , the detector spectral response can be made to cover the range from $1\text{ }\mu\text{m}$ to beyond $17\text{ }\mu\text{m}$. The advantages of this system arise from a number of features, notably: close lattice matching, high optical absorption coefficient, low carrier generation rate, high electron mobility and readily available doping techniques. These advantages mean that very sensitive infrared detectors can be produced at relatively high operating temperatures. HgCdTe continues to be developed as the material of choice for high-performance long-wavelength ($8\text{--}12\text{ }\mu\text{m}$) arrays and has an established market at the medium- ($3\text{--}5\text{ }\mu\text{m}$) and short-wavelength ($1\text{--}3\text{ }\mu\text{m}$) ranges.

In the LW band, the main competitive technologies are $\text{Pb}_{1-x}\text{Sn}_x\text{Te}$ (LTT) and multiple quantum well (MQW) detectors (usually using AlGaAs/GaAs technology). Work on LTT largely stopped in about the mid 1970s partly because the large dielectric constant made them unsuitable for photoconductors. However, there is more recent interest in large arrays of LTT photodiodes due to a potential cost advantage, but at present poor diode quality and excess noise makes them inferior to $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ on grounds of sensitivity alone. MQW arrays are essentially tuned to a wavelength, say $8.0\text{ }\mu\text{m}$, and need deeper cooling to suppress thermal leakage currents. The imaging performance can be good due to the absence of low-frequency noise sources but they have a much lower ultimate sensitivity than HgCdTe.

36.0.3 Introduction to Device Types

HgCdTe Photoconductive Arrays

A photoconductor usually comprises a small slab or element of material with two contacts. The aim is to detect the change in resistance of the element when the photon

flux is changed. The first HgCdTe devices were photoconductive because of the simplicity of the technology, and the relative ease of achieving near-ideal infrared performance and excellent reliability. HgCdTe photoconductive detectors have been in routine production since the early 1980s and are often called first-generation detectors. They are the key component of the US Common Module Thermal Imager and, in the form of the SPRITE detector, they feature in the UK Class II Common Module imager. Detectors for thermal imaging are most commonly fabricated with a peak response in the $8\text{--}12\text{ }\mu\text{m}$ atmospheric window region and are cooled to 80 K by means of a Joule–Thompson expansion cooler or, more recently, a Stirling engine refrigerator. They are also quite commonly made for operation in the $3\text{--}5\text{ }\mu\text{m}$ atmospheric window, and either use cooling to 80 K or employ Peltier (or thermoelectric) coolers to cool to around 200 K . Peltier-cooled MW detectors are used in many small handheld cameras and a whole host of heat sensing applications. The reliable performance, low levels of defects and easily understood physics has led to a long product life for photoconductive arrays. However the array size is limited and first-generation thermal imaging systems need to employ complex optics to scan the infrared image over the array to build up a scene. The main limitation to developing larger arrays arises from the difficulty involved with amplifying and multiplexing elements electronically on the focal plane. In consequence, there needs to be a separate electrical connection to each photoconductor so that they can be connected to low noise current amplifiers outside of the cryogenic encapsulation. For larger arrays of, say, more than several hundred elements the cryogenic encapsulations become cumbersome and expensive. Also, the power consumption can become a problem with too many elements, so this and cryogenics set a practical limit to the size of photoconductor arrays for commercial thermal imaging to a few hundred elements.

HgCdTe Photovoltaic Arrays

A photovoltaic device is essentially a light-sensitive diode. Photons absorbed in the semiconductor create electron–hole pairs, and the minority carriers diffuse to the p–n junction where they are “separated” and the voltage across the junction changes. Because there is an integration of carriers, the signal can be built up over a time called the integration time, and there is the potential for larger signals and better infrared sensitivity than can be achieved with photoconductors.

In the mid-1970s attention turned to the use of photovoltaic HgCdTe for thermal imaging applications. At

that time it was seen that, in the future, many infrared applications would need higher radiometric performance and/or higher spatial resolution than could be achieved with first-generation photoconductive infrared detectors. Photovoltaic arrays consume very little power, and can be easily multiplexed using an on-focal plane silicon chip, so they are well-suited to long linear and large, two-dimensional infrared arrays. Systems based upon such focal planes can be made smaller and lighter, with lower power consumption, and can result in much higher performance than systems based on first-generation detectors. Photovoltaic detectors can also have less low frequency noise, faster response time, and can avoid the need for complex scanning optics. To some extent these advantages are offset by the more complex processes needed to fabricate photovoltaic detectors, and so their development and industrialization have been slower, particularly for large arrays. Another point is that, unlike photoconductive detectors, the field of photovoltaic HgCdTe arrays shows a large variety of different material growth methods and device structures, often unique to individual companies and research organizations. The collective wealth of data on photovoltaic devices is therefore spread over a wide field.

Large two-dimensional and long linear arrays have the common feature that they are all mass-connected to a custom-designed silicon integrated circuit called a multiplexer or ROIC (for readout integrated circuit). The multiplexer performs the function of integrating the infrared signal and scanning the array. The evolution of large arrays was delayed by the slow emergence of silicon integrated circuits large enough to perform this

function economically. Another economic factor was matching the cost of first-generation infrared cameras which had a well-established market and had set a benchmark for display picture points and cost. Cost depends strongly on array size and infrared array pixels tend to be much larger than those commonly found in visible imaging arrays. Infrared arrays then tend to be physically large and, together with the extra complexity of the manufacturing process, relatively difficult to cost-reduce. The commercial viability of second-generation focal plane arrays has depended on matching the spatial resolution (number of elements in the array) and cost of existing first-generation systems, which was only really achieved in the 1990s.

HgCdTe Metal–Insulator–Semiconductor (MIS) Arrays

The MIS HgCdTe detector operates much like a silicon charge-coupled device (CCD). The MIS detector was the basic element in a family of “monolithic” HgCdTe arrays in which the detection, integration and multiplexing functions were all done within the HgCdTe material itself. Unlike the PV and PC detectors, the MIS device operates under strongly nonequilibrium conditions, with large electric fields in the deep depletion regions. This makes the MIS detector much more sensitive to material and process defects than the PV and PC detectors [36.2]. This sensitivity, particularly acute for LW devices, caused the monolithic approach to be abandoned in favor of various hybrid approaches where the IR photon detection is performed in HgCdTe, and the signal processing is restricted to the silicon multiplexer.

36.1 Applications and Sensor Design

Currently the most important market for HgCdTe arrays is in thermal imaging in the long (8–12 μm) and medium wavebands (3–5 μm). Often the detector is the performance-limiting component in the system, and it is necessary to use detectors with a sensitivity limited only by the random rate of arrival of photons from the scene (so-called background limited or BLIP detectors). In a narrow-gap semiconductor using both photoconductive and photovoltaic detectors, it is necessary to cool so that the thermal generation and associated excess noise are suppressed and the sensitivity becomes “BLIP-limited”. The choice of cooler is therefore a key technology in an infrared detector, and the common options are described here. One of the points to emphasize

is that the focal plane array is only one of a number of components that need to be optimized to preserve the BLIP performance. The optical design, cryogenics and signal processing are critical to maintaining the sensitivity of the focal plane array. The precision engineering involved in designing infrared detectors and coolers, particularly for survival in high shock and vibration environments, is still challenging.

The means of cooling depends on the detector type and application. For instance, photoconductive arrays often need a lot of cooling power because of the Joule heating on the focal plane and the need for many bond wires that add to the thermal load. Two-dimensional arrays, on the other hand, often consume little power

Fig. 36.1 Typical fast cooldown detector using Joule–Thompson cooling. (Courtesy of SELEX Infrared)

Fig. 36.2 Typical integrated detector: cooler assembly (IDCA). (Courtesy of SELEX Infrared)

and have few connections, allowing alternative cooling methods. Other considerations are cooldown time, power, weight, space-volume, robustness and life.

Historically the Joule–Thompson cooler was the first available method of cooling, relying on compressed gas bottles for power. The cooling power can be very high. Most first-generation detectors use Joule–Thompson

Fig. 36.3 Typical thermoelectrically cooled detector. (Courtesy of SELEX Infrared)

cooling. In more recent times the high cooling power has been routinely exploited in fast-cooldown applications. Figure 36.1 illustrates a typical fast-cooldown product, which can be cooled in a few seconds to liquid argon temperature (92 K). HgCdTe arrays are well-suited to this type of application because, unlike other materials such as indium antimonide or multiple quantum wells, BLIP operation is easily achieved at relatively high temperatures.

For most modern thermal imaging applications the normal means of cooling is a cryocooler based on the Stirling cycle, which can achieve temperatures as low as 55 K but is normally regulated at a temperature in the range 80–140 K. Figure 36.2 shows a typical integrated detector–cooler assembly (IDCA). The cutaway in Fig. 36.2 shows the front end of the detector in more detail. The infrared array is bonded directly on the cold finger of the cooler. To ensure only photons from the scene reach the detector, a cold stop or radiation shield is bonded to the cold finger. The cold stop will have internal baffles and special coatings to stop internal reflections and is a vital component for achieving BLIP operation of the array. The detector will have an optical pass-band filter that controls the upper and lower wavelengths. This will vary with the application, but typical bands are 3.2 to 4.2 μm , 3.7 to 4.9 μm or 7.7 to 10.6 μm . Two methods are commonly used. The filter can be incorporated in the cold stop, and is therefore cooled, producing a very efficient block to stray radiation, say from the dewar itself. Almost as good performance can be achieved with filters on the front window, and a well-designed cold stop.

The third common means of cooling is Peltier cooling (usually based on bismuth telluride devices). A typical detector is illustrated in Fig. 36.3. State of the art coolers can achieve temperatures as low as 180 K, but in general they are not as efficient as Stirling cryocoolers,

and the cooling performance can be poor in high ambient temperatures. Nevertheless the main strengths of long-term reliability, greater shock resistance and smaller weight and space-volume has created a large volume

market, especially for small photoconductor arrays. The temperature of 180 K is not quite cold enough for BLIP thermal imaging, and the applications tend to be those that can tolerate lower performance infrared detectors.

36.2 Photoconductive Detectors in HgCdTe and Related Alloys

The physics and technology of HgCdTe photoconductive detectors are described here. It also serves as an introduction to SPRITE detectors described in Sect. 36.3 and related work on other II–VI compounds summarized in Sect. 36.4.

Being quite a simple device, the photoconductor provides a convenient introduction to the physics and technology of infrared detectors made from HgCdTe. Figure 36.4 shows a photomicrograph and scanning electron microscope view of a typical photoconductive element. It comprises a small slab of material, typically 50 μm square and 8 μm thick with two ohmic contacts. The element illustrated has been “labyrinthed” to improve its performance. The device is operated using a constant current bias, supplied by means of a voltage source, and a series resistance, which is large compared to the detector resistance. The signal is measured as a voltage change across the detector, so that the device is essentially a radiation-sensitive resistor.

Fig. 36.4 Photomicrograph of 48-element photoconductive array using labyrinthed structures for enhanced responsivity. (Courtesy of SELEX Infrared)

36.2.1 Introduction to the Technology of Photoconductor Arrays

HgCdTe photoconductors were developed in the early 1970s when only bulk-grown material (from a Bridgman process or a solid state recrystallization process) was available. The simple device geometry allowed arrays to be manufactured by chemomechanical polishing of thick slices of material. Bulk material is still used because of the economic and convenient processes involved, but many workers [36.3–5] report arrays produced from LPE and MOVPE material. Because the electron mobility is many orders higher than the hole mobility in narrow-bandgap HgCdTe, it is advantageous to work with n-type material where the photoconductive gain is very high. n-type material can be manufactured directly, using the Bridgman growth process, or can be produced by two-temperature annealing. Chapter 14 describes the range of growth processes for HgCdTe. For photoconductors there is a requirement for a long minority carrier lifetime, which implies low levels of surface and bulk recombination centers. n-type material with a low doping level is ideal, because the fundamental carrier lifetime is more than adequate for most applications, and crystalline defects in n-type material appear to have a weak effect on the carrier lifetime. The quality of surfaces is critical because elements can be as thin as 4 μm . The technique most commonly used is to passivate the surfaces by anodic oxidation. The anodic oxide has a charge state that attracts electrons (accumulated surface) and provides an electric field which repels minority carriers, preventing them from interacting with surface recombination sites. The so-called surface recombination velocities are as low as 50 cm/s [36.6]. The individual elements are defined using a photomask and ion beam milling. As described later, ion beam milling results in a heavily doped n-type skin layer which also produces a low surface recombination velocity. Ion milling is also used to prepare the contact windows. The resulting highly doped n-type layer provides an excellent ohmic contact for electron flow, and a blocking contact to minority carrier holes. This condition enhances the minority carrier lifetime,

which leads to high signals and high sensitivity. As will be seen in the performance analysis, the device geometry and doping levels arising from the technology provide an excellent platform for producing sensitive detectors at relatively moderate cooling.

36.2.2 Theoretical Fundamentals for Long-Wavelength Arrays

Despite its apparent simplicity, a rigorous analysis of photoconductor operation is quite complex [36.7, 8]. Two-dimensional and three-dimensional treatments have been reported [36.9, 10], but the analysis here is restricted to a one-dimensional treatment.

For the purposes of simplicity, the analysis will concentrate on an n-type element, which is the most commonly used device structure. Consider a slab of HgCdTe of length l , width w and thickness t , having “ohmic” contacts formed to the end faces, and exposed to an infrared background flux of ϕ_b photons/cm².

Consider an electron–hole pair that is generated by a photon. Holes would drift towards the negative electrode with a velocity $\mu_a E$, where μ_a is the ambipolar mobility given by

$$\mu_a = (n - p)\mu_e\mu_h / (n\mu_e + p\mu_h), \quad (36.1)$$

where n and p are the electron and hole densities, and μ_e and μ_h are the electron and hole mobilities. The ambipolar mobility approximates to the minority carrier mobility in most situations, except when the temperature or the background flux is very high. At low values of the applied field, the average drift length of a minority carrier, $\mu_a E\tau$, is very much less than the detector length l , and recombination occurs predominantly in the bulk of the sample. The minority carrier density is uniform along the length of the sample (neglecting diffusion), and in the presence of background radiation, is given by:

$$p = p_0 + p_b \quad (36.2)$$

where p_0 is the thermal equilibrium concentration of holes, and

$$p_b = \eta\phi_b\tau/t \quad (36.3)$$

is the excess carrier density, in equilibrium with the background radiation, where η is the quantum efficiency.

Equations for the device parameters are given below. In large n-type detectors where the minority carrier drift length, $\mu_a E\tau$, is small compared to l , then the

responsivity in units of V/W is given by:

$$R_v = \frac{\eta V_0 \tau}{E_\lambda l w t n_0}, \quad \text{low bias} \quad (36.4)$$

where V_0 is the bias voltage and E_λ is the energy of a photon with wavelength λ .

At higher bias levels, the minority carrier lifetime in weakly doped n-type material can be made long enough to ensure that little recombination takes place before the carrier is swept to the negative contact (the so-called sweepout regime), such that $\mu_a E\tau > l$. The effective lifetime is reduced to a value τ_{eff} and, in the limit, to τ_a , where it is simply the average transit time. For simplicity we will assume that the equilibrium carrier densities are unchanged under bias. At the biases used in practical detectors, blocking contacts influence the carrier densities, and the effects must be taken into account.

The responsivity in sweepout is given by:

$$R_v(\text{max}) = \frac{\eta l}{2 E_\lambda w t n_0 \mu_h}, \quad \text{high bias} \quad (36.5)$$

Taking $\eta = 0.6$, $l = w = 50 \mu\text{m}$, $t = 8 \mu\text{m}$, $n_0 = 5 \times 10^{14} \text{ cm}^{-3}$, $E_\lambda = 0.1 \text{ eV}$ and $\mu_h = 450 \text{ cm}^2/\text{Vs}$, a value

Fig. 36.5 Characteristics of a 50 μm -square HgCdTe detector, operated at 80 K, as a function of bias voltage. (After SELEX Infrared)

for the maximum responsivity of $\approx 1 \times 10^5$ V/W is obtained. The responsivity observed in practical devices is lower than the calculated value, typically by a factor of two, because the anodic oxidation technique used to produce low recombination velocity surfaces also enhances the surface conductance, shunting the bulk of the device and lowering its resistance, i.e., n_0 is effectively increased in (36.5). The behavior of a typical device, showing the saturation in responsivity with bias, is shown in Fig. 36.5.

Responsivities in photoconductors tend to be low and there have been a number of novel techniques reported to boost the signal. Several methods concentrate on prolonging the life of minority carriers. One technique [36.11, 12] is to use a remote negative contact and an opaque screen to define the sensitive area so that holes are swept under the screen and contribute to the signal for longer. Another technique [36.13, 14] is to use a low recombination velocity n^+n contact to increase the responsivity by a factor of five by blocking the recombination of holes. Even larger increases have been obtained [36.15] by using a heterojunction contact, i.e., an epitaxially grown double layer is employed with a high x region of n -type HgCdTe between the active region and the metal contacts. The theory of devices with blocking contacts has been published in several papers [36.14–16]. Significant increases in responsivity have also been obtained by increasing the element resistance by defining a “meander path” or “labyrinth” device (Fig. 36.4).

The principal noise sources are generation–recombination ($g-r$) noise due to fluctuations in the optically or thermally generated free-carrier densities and Johnson–Nyquist noise, associated with the finite resistance of the devices. In addition, noise with a spectral power density varying with frequency as $1/f$ is usually observed, which has its origin in surface trapping and mobility modulation effects.

The equation for root mean square $g-r$ noise for a small device in strong sweep-out, and in which the background-induced carrier density $p_b\tau_a/2\tau \gg p_0$, is given by:

$$V_{g-r} = \frac{1}{n_0\mu_h t} \left(\frac{l^3 \eta \phi_b B}{w} \right)^{1/2}, \quad (36.6)$$

where B is the bandwidth. Using the same parameters as used above, and assuming a background flux of 5×10^{16} cm $^{-2}$ /s ($f/2$ cold shield and 300 K ambient temperature), the value for V_{g-r} in saturation is 5×10^{-9} V/Hz $^{1/2}$. This corresponds to a noise-equivalent resistance of approximately 1.5 k Ω , and since

the actual resistance of the device is $\approx 100 \Omega$ the design of low-noise preamplifiers is relatively straightforward. A plot of the $g-r$ noise for a practical device, with a peak response wavelength of 12 μ m, exposed to 300 K background radiation in an $f/2$ field of view, is shown in Fig. 36.5. The saturation of the noise at high bias is clearly demonstrated.

A necessary condition for background-limited operation is that $p_b \gg p_0$ or

$$\frac{\eta \phi_b \tau}{t} \gg \frac{n_i^2}{n_0}, \quad (36.7)$$

where n_i is the intrinsic carrier density, which is approximately 10^{13} cm $^{-3}$. The lifetime is itself a function of the background flux, but in reduced field of view, values in excess of 2 μ s are observed. Putting $\eta = 0.6$, $t = 10 \mu$ m and $n_0 = 5 \times 10^{14}$ cm $^{-3}$, we see that background-limited operation should be observed when $\phi_b > 1 \times 10^{15}$ cm $^{-2}$ /s, i.e., a field of view greater than about 5°, and for a background scene temperature of 300 K.

It is generally the case [36.17–19] that the lifetime in good-quality n -type HgCdTe, with a cut-off wavelength near 10 μ m at 80 K, is determined by Auger 1 recombination, except possibly at very low donor concentrations near 1×10^{14} cm $^{-3}$, where Shockley–Read recombination may be significant. Auger 1 is essentially impact ionization by electrons in the high-energy tail of the Fermi–Dirac distribution, which have energies greater than the band gap E_g . An expression for Auger lifetime is:

$$\tau = 2\tau_{Ai1} \frac{n_i^2}{n(n+p)}, \quad (36.8)$$

where τ_{Ai1} is the intrinsic Auger 1 lifetime, which has a value of approximately 1×10^{-3} s.

The sensitivity of a detector is often described by the parameter called the detectivity. The detectivity (or D^*) is a signal-to-noise parameter normalized for area and bandwidth, and is used to compare photoconductor performance. Dividing the responsivity by the $g-r$ noise expression gives

$$D_\lambda^* = \frac{\eta^{1/2}}{2E_\lambda} \left(\frac{1}{\phi_b} \right). \quad (36.9)$$

The limiting D^* in zero background flux is given by

$$D_\lambda^* = \frac{\eta}{2E_\lambda} \left(\frac{2\tau_{Ai1}}{n_0 t} \right)^{1/2}. \quad (36.10)$$

Using the values for the parameters as taken earlier

$$D_\lambda^* = 1 \times 10^{12} \text{ cmHz}^{1/2}/\text{W} \quad (36.11)$$

and experimental results close to this value have been reported [36.19].

In the high-bias sweep-out condition, photoconductive detectors can have a frequency response of several MHz, the response time being determined by the transit time of the holes between the electrodes, $l^2/\mu_h V_0$, rather than the excess carrier lifetime. The effect of bias on time constant is shown for a practical device in Fig. 36.5.

Detectors for space applications, with cut-off wavelengths of between 15 and 16 μm , have been reported with D^* of $3\text{--}4 \times 10^{11} \text{ cm Hz}^{1/2}/\text{W}$, when operated at 60 K in a background flux of $2 \times 10^{15} \text{ photons/cm}^2 \text{ s}$ [36.18].

36.2.3 Special Case of Medium-Wavelength Arrays

Detectors operating in the 3–5 μm range, with an aperture of $f/1$ or faster, normally have near-BLIP performance. Figure 36.6 shows the D^* versus cut-off wavelength for n-type photoconductive detectors. The theoretical maxima include Auger generation and radiative generation only. The experimental points are for 230 μm square n-type detectors, except where indicated. Small detectors in very low background flux conditions are expected to be Johnson noise-limited due to sweep-out. The limiting value of detectivity for n-type detectors in zero background flux [36.20, 21] is

$$D^*_{\lambda} = \frac{\eta l}{4 E_{\lambda} t^{1/2}} \left(\frac{q}{kT} \right)^{1/2} \left(\frac{b}{\mu_h n} \right)^{1/2} \cong 1.7 \times 10^{19} \left(\frac{b}{\mu_h n} \right)^{1/2}, \quad (36.12)$$

where the numerical value is obtained assuming $l = w = 100 \mu\text{m}$, $t = 10 \mu\text{m}$, $\eta = 0.7$ and $E_{\lambda} = 0.25 \text{ eV}$.

36.2.4 Nonequilibrium Effects in Photoconductors

So far, the modeling of photoconductive devices has assumed equilibrium conditions for carrier densities. In reality, the application of bias fields results in departures from thermal equilibrium. An example occurs at the positive contact, where the highly doped buffer layer results in negligible hole emission (so-called excluding contact). When the bias is applied, no holes can be in-

Fig. 36.6 D^*_{λ} versus cut-off wavelength for n-type photoconductive detectors. *Solid square* 80 K 60° FOV ($50 \times 50 \mu\text{m}^2$); *open square* 190 K 80° FOV; *solid circle* 190 K 60° FOV; *open circle* 220 K 2π FOV; *open triangle* 295 K 2π FOV; *solid line* Theoretical maximum in equilibrium (Auger 1, Auger 7 and radiative generation); *dotted line* BLIP (60° FOV, 30% reflection loss). (After SELEX Infrared, with permission)

jected into the material to sustain the flow of holes in the bulk away from the contact. As a consequence, p is reduced for some distance away from the contact. In order to maintain near space-charge neutrality, n also falls to a value close to the extrinsic value. The dominant thermal generation process in n-type material is Auger 1. For the example shown, n is reduced by a factor of about thirty, which would reduce the Auger 1 generation rate by the same factor, and increase the detectivity by a factor of more than five if other noise sources, such as Shockley–Read, were low. In devices with noninjecting contacts this effect results in a significant operating temperature advantage.

36.3 SPRITE Detectors

The SPRITE detector was invented in the early 1970s [36.20, 22, 23] and it forms the basis of the UK common module detector, produced in large numbers. A thorough description of the device is reported in [36.24]. It is a very elegant method of amplifying the sensitivity of a photoconductive device. It is also a very compact device, which enables highly efficient radiation shielding and economical use of material. SPRITE detectors are used in serial-parallel scan imaging systems, because they perform a time-delay and signal integration function, in addition to a detector function. The operating principle of the device is illustrated in Figs. 36.7a and 36.7b. It consists of a strip of n-type HgCdTe, typically 700 μm long, 60 μm wide and 10 μm thick, with three ohmic contacts. A constant-current circuit provides bias through the two end contacts. The third contact is a potential probe for signal read-out. There are two important points concerning the operation of the device. Firstly, the bias field must be sufficiently high to ensure that excess minority carriers, generated along the filament length, can reach the negative end contact before recombination occurs. Secondly, the bias field must be chosen so that the ambipolar drift velocity V_a is equal to the image scan velocity. SPRITE detectors have been commonly used in 8-row, 16-row and 24-row arrays and are commercially available in these forms.

Consider now an image feature scanned along the filament, as illustrated in Fig. 36.7a. The density of excess carriers in the filament, at a position corresponding to the illuminated element, increases during the scan, as illustrated in Fig. 36.7b. The carrier concentration increases during the scan as $[1 - \exp(-x/v_s\tau)]$, where x is the distance from the positive bias contact along the scan direction, and τ is the excess carrier lifetime. When the illuminated region enters the readout zone, the increased conductivity modulates the voltage on the contact and provides an output signal. Since the integration time of the signal flux, which is τ in a long element (or L/v_a in a shorter element), is greater than the dwell time on a conventional discrete element in a fast-scanned, serial system, a larger conductivity modulation and, hence, a larger output signal is observed.

Therefore, the SPRITE detector continuously performs a time-delay-integration function and the signal-to-noise ratio is improved as a result of coherent integration of the signal and incoherent integration of the noise. The net gain in the signal-to-noise ratio is proportional to the square root of the integration time. For an amplifier-limited or a Johnson noise-limited detector, the gain is proportional to the integration time.

The viability of the device depends on three aspects. The minority carrier lifetime must be maximized to give the longest possible integration length, the speed of the carriers (holes) must match a practical image scanning speed and the thermal spread of the carriers must be minimized as this will blur the image. In practice, this implies the need for large τ values to provide long integration times, and low minority carrier diffusion lengths Q_h to provide good spatial resolution. The material properties obtained for low carrier concentration n-type HgCdTe (as shown in Table 36.1) proves this to be a very suitable material for the device. Lifetime values of about 2 μs are obtained in alloy compositions suitable for 8–14 μm , 80 K operation, with an extrinsic carrier density of $\approx 10^{14} \text{ cm}^{-3}$. Recombination is principally by the Auger 1 process in these compositions, and longer

Fig. 36.7 The operating principle of a SPRITE detector

Table 36.1 Properties of n-type HgCdTe

Waveband (μm)	Operating temperature (K)	Lifetime (μs)	Hole mobility (μ_h) ($\text{cm}^2/\text{V/s}$)	D_h (cm^2/s)	Diffusion length Q_h (μm)
8–14	80	2–5	480	3.2	25
3–5	230	15–30	100	2.0	5

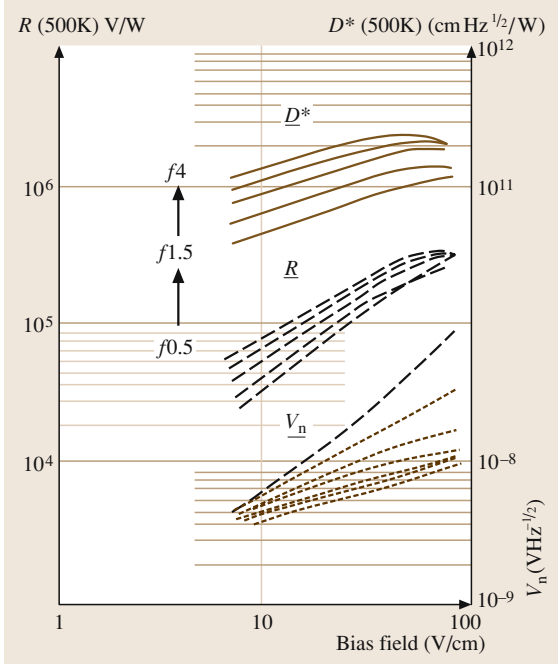

Fig. 36.8 Typical performance of a LW SPRITE detector ($\lambda_c = 11 \mu\text{m}$, $T = 77 \text{ K}$). (After [36.25])

lifetimes, up to $\approx 10 \mu\text{s}$ (achievable in low-background conditions), may be obtained from lower carrier density material. Lifetime values of 15–30 μs are obtained in compositions used for 3–5 μm operation at thermoelectric temperatures. The low hole mobility in HgCdTe results in short diffusion lengths, even with long lifetimes, yielding a spatial resolution in the 8–14 μm band SPRITE devices of $\approx 50 \mu\text{m}$ and $\approx 100 \mu\text{m}$ in 3–5 μm devices if the full integration is used.

The detectivity for a long, background-limited device in which $L \gg \mu_a E \tau$ and $\eta \phi_b \tau / t \gg p_0$ is

$$D_{\lambda}^* = \frac{\eta^{1/2}}{2E_{\lambda}} \left(\frac{1}{\phi_b w} \right)^{1/2} \left\{ 1 - \frac{\tau}{\tau_a} [1 - \exp(\tau_a/\tau)] \right\}^{1/2}, \quad (36.13)$$

where w is the element width, l is the length of the readout region, and $\tau_a = \ell/\nu_a$ is the transit time through the readout region. At sufficiently high scan speeds, such that $\tau_a \ll \tau$,

$$D_{\lambda}^* = (2\eta)^{1/2} D^* (\text{BLIP}) \left(\frac{l}{w} \right)^{1/2} \left(\frac{\tau}{\tau_a} \right)^{1/2}. \quad (36.14)$$

It is convenient to express D_{λ}^* in terms of the pixel rate S which, for a nominal resolution size of $w \times w$, is ν_s/w .

Thus, in the high scan speed limit

$$D_{\lambda}^* = (2\eta)^{1/2} D^* (\text{BLIP}) (S\tau)^{1/2}. \quad (36.15)$$

The number of background-limited elements that would be required to provide the same performance in a serial array is

$$N_{\text{eq}} (\text{BLIP}) = 2S\tau. \quad (36.16)$$

For example, a 60 μm wide element scanned at a speed of $2 \times 10^4 \text{ cm/s}$, and with τ equal to 2 μs , gives $N_{\text{eq}} (\text{BLIP}) = 13$.

The performance achieved in the 8–12 μm band is illustrated in Fig. 36.8. It may be seen that very high values of responsivity are obtained, as well as high values of D^* . The latter increases with the square root of the bias field, except at the highest fields, where Joule heating raises the element temperature. The detectivity increases with increasing cold-shield effective f /number to about $f/4$. It is, in practice, desirable to operate with efficient cold shielding with an f /number of ≥ 2 to avoid reductions of the carrier lifetime resulting from increased carrier density due to the background flux. An example of the results obtained from a SPRITE operating in the 3–5 μm band is shown in Fig. 36.9. Useful performance

in this band can be obtained at temperatures up to about 240 K.

The spatial resolution of the SPRITE detector when the scan velocity and the carrier velocity are matched throughout the device length, is determined by the diffusive spread of the photogenerated carriers and the spatial averaging in the readout zone. This may be expressed through the modulation transfer function (MTF):

$$\text{MTF} = \left(\frac{1}{1 + k_s^2 Q_h^3} \right) \left[\frac{2 \sin(k_s l / 2)}{k_s l} \right], \quad (36.17)$$

where k_s is the spatial frequency. The behavior of noise in the device at high frequencies is described in several papers [36.26,27]. Some optimization of the shape of the filament has been carried out, involving a tapering of the read-out zone and a slight tapering of the main body of

the element [36.28]. Following these modifications, very good agreement with (36.17) was obtained. In practice, the length of the read-out zone can be chosen sufficiently small that the diffusion term sets the limit. It was believed initially that this limit was fundamental, and that the only way in which it could be reduced was to restrict the integration by means of a shorter device. In fact, several different methods have been discussed [36.29] by means of which better spatial resolution can be obtained at the expense of additional power dissipation on the focal plane. The technique that has found most favor with system designers has been to increase the focal length of the detector lens in an afocal system, usually by employing anamorphic optics [36.30]. This allows the diffusion spot radius to be reduced below the diffraction spot radius.

36.4 Photoconductive Detectors in Closely Related Alloys

There has been some interest in developing alternative ternary alloys to replace HgCdTe, as from theoretical considerations it has been shown that the already weak Hg–Te lattice bond is further destabilized by alloying with CdTe [36.31]. It is predicted that the Hg–Te bond may be more stable in alternative alloys, leading to materials with increased hardness and detectors with better temperature stability. Apart from Cd and Zn, the other elements capable of opening up a bandgap in the semimetals HgTe and HgSe are Mn and Mg. In the case of Mg, little reinforcement of the Hg–Te bond occurs at compositions appropriate to 10 μm detectors, and in the case of $\text{Hg}_{1-x}\text{Cd}_x\text{Se}$, difficulties have been experienced in obtaining type-conversion and lightly doped n-type material. Most of the attention, therefore, has been focused on $\text{Hg}_{1-x}\text{Zn}_x\text{Te}$ and $\text{Hg}_{1-x}\text{Mn}_x\text{Te}$. As mentioned in the introduction, the technology and general properties of these materials are very similar to HgCdTe and much of the device processing is common to both. The status of the research is described by [36.32].

The hardness of $\text{Hg}_{1-x}\text{Zn}_x\text{Te}$ is about a factor of two better than HgCdTe and interdiffusion about one tenth, so this compound offers promise of competing with HgCdTe. However $\text{Hg}_{1-x}\text{Zn}_x\text{Te}$ presents more difficult material problems than HgCdTe. For instance, the separation of the liquidus and solidus curves is large and leads to high segregation coefficients. Also, the solidus lines are flat, leading to a strong composition dependence on growth temperature, and a very high mercury

overpressure is needed for bulk crystal growth. The best crystals have been grown by the traveling heater method (THM). A D_λ^* value of $8 \times 10^9 \text{ cm Hz}^{1/2}/\text{W}$ has been quoted [36.33] for photoconductive detectors at 80 K prepared from LPE material, a value substantially lower than that typical of HgCdTe devices. 10.6 μm laser detectors with D_λ^* values in the range $3\text{--}6.5 \times 10^7 \text{ cm Hz}^{1/2}/\text{W}$ have been reported [36.34], comparable to those observed in equilibrium devices in HgCdTe. The most promising results, however, are those for long-wavelength detectors, of interest for space applications, with cut-off wavelengths as long as 17 μm [36.35]. The D_λ^* values were $8\text{--}10 \times 10^{10} \text{ cm Hz}^{1/2}/\text{W}$, measured at 65 K. Photodiodes have been produced by all of the established techniques, including ion implantation into THM material [36.36] and Hg diffusion into isothermal vapor phase material [36.37]. Both report comparable performance to HgCdTe diodes. The maximum annealing temperature is reported to be 10 to 20° better than HgCdTe. Challenges for the future will be to match the uniformity and defect levels of HgCdTe.

$\text{Hg}_{1-x}\text{Mn}_x\text{Te}$ is a semimagnetic narrow-gap semiconductor, but strictly it is not a II–VI ternary compound because Mn is not a group II element but is included here for completeness. $\text{Hg}_{1-x}\text{Mn}_x\text{Te}$ also has material disadvantages compared to HgCdTe and HgMnTe crystals need to be much more uniform in composition to achieve the same wavelength uniformity. For epitaxial growth the strong variation of lattice parameter with composition is also thought to be a disadvantage com-

pared with HgCdTe. Photodiodes have been produced by Hg diffusion into THM material and VPE material

grown on CdMnTe substrates, but the RoA values were low [36.38] and not yet competitive with other materials.

36.5 Conclusions on Photoconductive HgCdTe Detectors

Photoconductive HgCdTe detectors have been very successful in producing arrays of up to a few hundred elements or the equivalent in SPRITEs, for use in first-generation thermal imaging systems. The fundamental properties of HgCdTe have been found to be near-ideal for the fabrication of high-responsivity single elements, and for the fabrication of SPRITEs with very high responsivity and detectivity together with good spatial resolution. Frequency response into the MHz region is obtained from both types of device due to sweep-out effects. The limitations of photoconductive detectors are apparent when very large focal

plane arrays are required. The low impedance of the photoconductor makes it unsuitable for coupling to direct injection gates of silicon charge transfer devices or MOS field effect transistors, therefore each element requires a lead-out through the vacuum encapsulation to an off-focal plane amplifier. The complexity of the dewar, therefore, limits the size of the array. This problem is considerably reduced in the SPRITE, but in this case, the effect of the Joule heating in the elements on the heat load of the cooler limits the maximum array size. For comprehensive reviews see [36.8, 39–41].

36.6 Photovoltaic Devices in HgCdTe

Photovoltaic arrays have inherently low power consumption and can be easily connected to a silicon integrated circuit to produce a retina-like focal plane array. Such arrays are key to so-called second-generation thermal imaging cameras which break through the performance limits imposed by photoconductive arrays in first-generation cameras. Photovoltaic devices tend to fall into two categories: long linear arrays of long-wavelength (8–12 μm) diodes and matrix arrays of medium-wavelength (3–5 μm) diodes.

Long linear arrays are required for systems with just one dimension of scanning. Here HgCdTe is the sensor material of choice because the stringent sensitivity requirements of these systems demands a high quantum efficiency and near BLIP-limited performance detectors. Development work in the 1980s and 1990s in the USA and Europe has led to a family of detectors for long-waveband thermal imaging, such as the US SADA II system based on a 480×6 format or the UK STAIRS “C” system based on a 768×8 array format (producing a high-definition 1250×768 image). In the detector examples quoted there are six or eight rows of diodes and the signal from each row is delayed in time and added to provide an enhancement. This is called time delay and integration (TDI). An important advantage of this scheme is that defective pixels can be deselected, so typically the STAIRS system will only use the best six of

Fig. 36.10 Medium-wavelength infrared image from a 384×288 element array (OSPREY) and the Kenis System. (Courtesy Denel Ltd)

the eight diodes in one channel. Consequently the detector performance can be relatively insensitive to defects in the HgCdTe, and this is the reason why LW long linear arrays have reached maturity much earlier than LW matrix arrays.

Long linear arrays can also use the MW band, but the flux levels are over an order less than the LW band and the performance is compromised by the short integration time in a scanned system. MW detectors then tend to use matrix arrays where the integration time can approach the frame time. The problem of point defects is considerably reduced in the medium waveband and large 2-D arrays are more practical. The emphasis for MW detectors is on developing wafer-scale processes to provide large, economical 2-D arrays for staring thermal imaging cameras. The MW band thermal imaging market is concentrated on arrays using half-TV (320×256 or 384×288) or full-TV formats (640×480 or 640×512), and is divided between indium antimonide (InSb), HgCdTe and platinum silicide. Broadly, manufacturing companies from the USA and Israel tend to prefer InSb, and European and some US companies have specialized in HgCdTe. Currently, infrared cameras based on HgCdTe arrays are in production and are producing remarkable sensitivities, over an order better than first-generation cameras. Figure 36.10 shows a representative image from a state of the art HgCdTe 2-D array.

Unlike photoconductive arrays, manufacturers use a variety of different technologies for photovoltaic arrays. Sections 36.6.1 to 36.6.3 describe the theory of photovoltaic detectors and the fundamental principles behind HgCdTe device technology. These principles help to explain the various approaches used by manufacturers to produce detectors in both the LW and MW bands described in Sects. 36.6.4 to 36.6.7. Section 36.6.8 describes the research and development progress in so-called Gen III (third-generation thermal imaging equipment) programs aimed at advanced infrared detectors.

36.6.1 Ideal Photovoltaic Devices

The current–voltage characteristic for an ideal diffusion-limited diode exposed to a photon flux ϕ_λ is given by:

$$I_d = I_s \left(\exp \frac{qV_d}{kT} - 1 \right) - qA\eta\phi_\lambda, \quad (36.18)$$

where I_d is the diode current, I_s is the diffusion current, V_d is the diode bias voltage (taking negative values in reverse-bias), η is the quantum efficiency and A is

the detector area. The second term in (36.18) is the photocurrent, I_{ph} . The quantum efficiency is given by:

$$\eta = (1 - R)[1 - \exp(-\alpha_\lambda t)]F, \quad (36.19)$$

where R is the reflectivity of the front surface, normally minimized by an antireflection coating, α_λ is the absorption coefficient, t is the sample thickness, which is typically around $6\text{--}10\ \mu\text{m}$ to give adequate absorption in HgCdTe detectors, and F is a geometry factor which describes the number of photogenerated carriers within the pixel which reach the junction before recombining.

The condition that the detector be background limited is crucial for high-performance systems, and to meet this condition the internal thermal generation must be much less than the photon generation in the lowest flux case, i.e. $I_s \ll I_{ph}$. By differentiating (36.18), I_s is given by kT/qR_0 , where R_0 is the zero bias resistance. The condition for background-limited performance is therefore often written as $R_0 \gg kT/qI_{ph}$, and this is the origin of the commonly used figure of merit, R_0A . As an example, in the case of a long waveband system, say $10\ \mu\text{m}$ cut-off, with an F2 optic and a lowest background scene temperature of -40°C , an R_0A of greater than $30\ \Omega\text{cm}^2$ is required. Detectors need to be cooled sufficiently to suppress thermally generated currents, but there are always pressures to avoid very low temperatures to give savings in power and cooldown time and better engine reliability. This is particularly the case for cut-off wavelengths longer than $10\ \mu\text{m}$, and detector technologies have emerged that provide high R_0A as a first priority.

The white noise current at low frequencies is given by:

$$i_n^2 = 2qI_s \left[1 + \exp \left(\frac{qV_d}{kT} \right) \right] B + 2q(qA\eta\phi_\lambda)B, \quad (36.20)$$

where B is the bandwidth in Hz. In the absence of photocurrent, the noise at zero bias is equal to the Johnson noise, $4kTB/R_0$. In reverse bias it tends to the normal expression for shot noise, $2q(I_s + I_{ph})B$. Note that the mean-square shot noise in reverse bias is half that of the Johnson noise at zero bias.

The current responsivity is $\eta q/E_\lambda$, where E_λ is the photon energy, and this leads to the general expression for detectivity:

$$D_\lambda^* = \frac{\eta q}{E_\lambda} \sqrt{\frac{A}{i_n^2}}. \quad (36.21)$$

When the photocurrent exceeds the diffusion current, the device is said to be background limited (BLIP), and

the first term in (36.20) can be ignored. The background-limited detectivity is then given by:

$$D_{\lambda}^* (\text{BLIP}) = \frac{1}{E_{\lambda}} \sqrt{\frac{\eta}{2\phi_{\lambda}}} \quad (36.22)$$

Note that, in comparison with (36.9), the background-limited detectivity of a photodiode is a factor of $\sqrt{2}$ better than that of a photoconductor.

36.6.2 Nonideal Behavior in HgCdTe Diodes

In medium-waveband arrays the current–voltage (I–V) characteristic is usually close to ideal, but at longer wavelength a number of leakage currents can impact on the I–V characteristics and degrade the performance of the detector. Figure 36.11 illustrates a typical I–V characteristic for a LW diode, along with two types of HgCdTe photodiode, a planar diode and a via-hole diode. The diagram illustrates how factors such as thermally generated current, shunt resistance and breakdown currents at high bias can effect the diode behavior. The performance can be degraded directly; for exam-

Fig. 36.11 Types of HgCdTe diode and a typical current–voltage characteristic for a LW diode showing main nonideal features

ple, extra currents produce white noise which may be significant if the leakage currents are of the same order as the photocurrent. In addition, some leakage current mechanisms are associated with trapping or tunneling and often produce excess, low-frequency noise (often called $1/f$ noise due to its typical trend with frequency). However an additional constraint arises from the need to inject photocurrent into a silicon multiplexer. The simplest method is called direct injection and literally means injection of the photocurrent into a common gate MOSFET. A capacitor on the drain performs the integration. Good injection efficiency is only achieved if the diode has a dynamic resistance higher than the input impedance of the MOSFET. Unless the dynamic impedance of the diode is high enough, the signal can be attenuated, additional noise added and nonlinearity generated in the response. Electronic correction for nonuniformity in the array is essential in IR detectors and nonlinearity can add spatial noise to the image after nonuniformity correction.

Achieving a high dynamic resistance has been a driver in the development of most infrared technologies. Very roughly there is a distinction between medium-wavelength (MW) arrays with cut-offs up to $6\text{ }\mu\text{m}$ and long-wavelength (LW) arrays. In MW arrays high injection efficiencies are routinely seen because the photodiodes are near-ideal. In the long waveband there will be a limit to the upper cut-off wavelength and/or flux levels that routinely allow high injection efficiencies using direct injection.

In order to inject the photocurrent signal efficiently into the input MOSFET, the input impedance of the MOSFET must be much lower than the internal dynamic resistance of the photodiode. The input impedance of a MOSFET is a function of the source-drain current (in this case the total diode current) and is usually expressed in terms of the transconductance, g_m , given by $qI_d/(nKT)$ for low injected currents (n is an ideality factor that can vary with technology usually in the range 1–2). The expression for injection efficiency ε given approximately by:

$$\varepsilon = \frac{R_V I_d}{R_V I_d + \frac{nKT}{q}} \quad (36.23)$$

where R_V is the dynamic impedance of the diode and I_d is the total injected diode current equal to I_{ph} in the background-limited case.

In the background-limited case, (36.23) becomes a simple function of $I_{ph} R_V$. For a very high performance system requiring an efficiency of 99.9%, the value of $I_{ph} R_V$ approaches 10 V, and in systems with slow

optics and low background temperatures, the requirement for R_v can exceed $10^9 \Omega$. In the long waveband this can present a technological challenge. There are more complex injection circuits that effectively reduce the input impedance and allow lower HgCdTe resistances to be used, but these require more silicon area and a higher power consumption, which may not be practical. The choice of buffer circuit depends on the application, and good comprehensive summaries are presented by [36.42, 43].

For most applications the detector performance depends on operating the diode in a small reverse bias where the dynamic resistance is at a maximum. It is then necessary to minimize extraneous leakage currents. The control of these leakage currents and the associated low-frequency noise is therefore of crucial interest to the device engineer. The origin of the leakage currents and the measures that are taken to minimize them are explained here in detail.

36.6.3 Theoretical Foundations of HgCdTe Array Technology

Good detailed summaries of photodiode fundamentals have been provided by [36.44, 45] and the reference lists contained therein. The purpose of this section is to highlight the key issues that control the thermal generation, leakage currents and quantum efficiency in detectors. From this analysis it is easier to understand the measures taken by detector manufacturers to make practical high-performance detectors.

Thermal Diffusion Currents in HgCdTe

Expressions for the diffusion current in photovoltaic devices have been derived [36.44] and the fundamental R_0A expression is given in (36.24):

$$R_0A(n - \text{side}) = \frac{N_d}{qn_i^2} \sqrt{\frac{kT\tau_h}{q\mu_h}}, \quad (36.24)$$

where N_d is the net donor concentration on the n-side, n_i is the intrinsic carrier concentration, which dominates the temperature dependence, and τ_h and μ_h are the minority carrier lifetime and mobility, respectively.

A similar expression describes the contribution of the p-side. In practice, the diffusion length L in normally doped HgCdTe is often larger than the 6–10 μm needed for effective infrared radiation absorption. In this case, the volume available for the generation of diffusion current is restricted, and a suitable modified expression

is:

$$R_0A(n - \text{side}) = \frac{kTN_d\tau_h}{q^2n_i^2\tau_n}, \quad (36.25)$$

where τ_n is the thickness of the n-type material.

In the case of L being greater than t_n , the surfaces and contacts can act as sources of extra diffusion current if the surface recombination velocity is greater than the diffusion velocity D/L . It is essential to ensure properly passivated surfaces and for contacts employ a minority carrier barrier, such as a higher doped or wider band gap layer under the metal contact.

The behavior of (36.25) with doping depends upon the dominant recombination process, i.e. radiative, Auger or Shockley-Read (S-R). Auger recombination in HgCdTe is a phenomenon involving the interaction of three carriers. The Auger 1 lifetime in n-type material is due to the interaction of two electrons and a hole and is generally minimized by using a low carrier concentration on the n-side. Fortunately it is relatively easy to produce low carrier concentrations in n-type material ($< 5 \times 10^{14} \text{ cm}^{-3}$).

In p-type material Auger recombination involves two holes and an electron and is referred to as Auger 7. The lifetime in p-type HgCdTe is reported [36.46–48] to show an inverse, linear dependence on doping, and this is attributed to the Shockley-Read process. S-R recombination is often associated with the Hg vacancy and can be modeled by a strong donor level located $\approx 30 \text{ mV}$ from the conduction band, which appears to be independent of composition in the $x = 0.2$ to 0.3 range. The density of these donor S-R centers is said to be proportional to the Hg vacancy concentration, but lower by a factor of ≈ 20 . If Hg vacancies are replaced by acceptor atoms such as Cu, Ag, Na or Au, the lifetime can be increased by over an order of magnitude. The use of extrinsic doping is an effective way to reduce thermal currents from the p-side in homojunction devices.

In order to engineer a detector with low thermal diffusion current (or high R_0A) it is important to recognize that it is only necessary to use one side of the junction for collecting photocurrent; the other side, in principle, can be made with a wider bandgap, thereby minimizing the thermal current contribution. Devices with layers of different band gaps are called heterostructures. The most common design is to use a wider bandgap on the p-side to reduce the thermal diffusion current and use the n-side as an absorber taking advantage of the long minority carrier diffusion lengths to maximize the quantum efficiency.

Thermal Generation Through Traps in the Depletion Region

The thermal generation rate g_{dep} within the depletion region via traps is given by the usual Shockley-Read expression:

$$g_{\text{dep}} = n_i^2 (n_1 \tau_{n0} + p_1 \tau_{p0})^{-1}, \quad (36.26)$$

where n_1 and p_1 are the electron and hole concentrations which would be obtained if the Fermi energy was at the trap energy, and τ_{n0} and τ_{p0} are the lifetimes in the strongly n-type and p-type regions.

The leakage current is often known as g–r current. Normally, one of the terms in the denominator of (36.26) will dominate, and for the case of a trap at the intrinsic level, n_1 and $p_1 = n_i$, giving $g_{\text{dep}} = n_i/\tau$. It is the weaker dependence on n_i , and therefore on temperature, that distinguishes generation within the depletion layer from thermal diffusion current.

Where the depletion region intercepts the surface, there is often enhanced generation due to the presence of a high density of interface states. This can be exacerbated if the surface passivation is not properly optimized to give a flat band potential at the junction. In an extreme case, the surface on one side of the junction may become inverted, creating an extension of the depletion layer along the surface, and leading to high generation currents. A practical solution to this mechanism is to widen the band gap in the material where the junction intercepts the surface, so-called heteropassivation. This can be achieved by using a thin film of CdTe together with a low-temperature anneal [36.49], and this is the commonest passivation technique used by manufacturers.

Interband Tunneling

Due to the very low effective mass of the electron in HgCdTe, direct band-to-band tunneling can occur from filled states in the valence band to empty states at the same energy in the conduction band. An expression for the current due to this process has been developed by [36.50]. The tunneling current increases very rapidly as the applied voltage or doping is increased, or the band gap or temperature is decreased. It is the normal modern practice to use low doping on one side of the junction to minimize interband tunneling under normal operating conditions, but nevertheless, at low temperature or for very long wavelength devices, interband tunneling can become dominant.

Trap-Assisted Tunneling

Trap-assisted tunneling is generally accepted to be one of the main causes of leakage current and excess noise in

LW diode arrays, but it is not a fundamental limitation, often being associated with impurities or structural defects within the depletion region. The definition of a trap is a center with a capture coefficient for minority carriers many times larger than that for majority carriers (otherwise it is a generation center). The role played by traps in the depletion region is very complicated, allowing for three possible two-step processes: thermal-tunnel, tunnel-thermal and tunnel-tunnel. The nonthermal step can include tunneling of electrons from the valence band to traps, and tunneling from the traps to the conduction band.

The formulation for trap-assisted tunneling in HgCdTe has been developed [36.51, 52] based upon original work in silicon [36.53]. Models based on a thermal-tunnel process can explain the bias-dependent behavior of reverse current in long-wavelength diodes [36.54–56].

A trap-assisted tunneling process can explain the observed behavior of n⁺–p diodes [36.57]. The process involves a thermally excited, bulk Shockley-Read center, modeled for the special case of the trap residing at the Fermi level. The physical picture for this assumption is that there is a uniform distribution of trapping centers throughout the bandgap and the barrier for tunneling is lowest at the uppermost center that is still occupied. Hence, the occupied trapping center that coincides with the Fermi level has the highest transition probability and plays the dominant role in the thermal trap-assisted tunneling process. This model helps to explain several unusual properties, such as an observed reduction in leakage current when the temperature is reduced or the doping level increased. Note that this is in contrast to direct band-to-band tunneling. Also, there is a much weaker dependence on diode bias voltage. The model also predicts the commonly observed “ohmic” region illustrated in Fig. 36.11 at a bias of around –100 mV.

The physical origin of the trap has not been established yet but it appears to be an acceptor-type impurity or defect within the depletion region. The population of such traps is likely to be dependent on the HgCdTe material and the junction forming technology and so the quality of LW diodes is highly process-specific.

Impact Ionization

Underlying trap-assisted tunneling, a more fundamental source of leakage current has been proposed, which is called impact ionization.

The reverse bias characteristics of homojunction arrays often show behavior that is not easily explained by conventional trapping mechanisms. For instance, the

product of p-side diffusion currents (including photocurrent) and reverse bias resistance is often observed to be insensitive to temperature and cut-off wavelength over a wide range (at least 4–11 $\mu\text{m s}$), and the current increases much more slowly with reverse bias than tunneling models would predict. A model based upon an impact ionization effect within the depletion layer gives a good fit to these observations [36.21]. The effect arises because in HgCdTe the electron scattering mechanisms tend to be weak and hot electrons can penetrate deep into the conduction band where they readily avalanche. Leakage current arises because extra electron-hole pairs are created within the depletion region due to impact ionization by minority carrier electrons from the p-side. The leakage mechanism has been confirmed to have a linear relationship with optically injected minority carriers over a wide temperature range [36.58].

Calculations have been performed on the effect of impact ionization on homojunction performance as a function of the doping levels [36.59]. These predict that to achieve a high dynamic resistance and therefore a high injection efficiency, the n-side doping must be very low. Routinely achieving low carrier concentrations ($< 5 \times 10^{14} \text{ cm}^{-3}$) is an important aim for homojunction technology. Most manufacturers introduce a donor, such as indium, to the crystal to control the n-type level to around $3\text{--}5 \times 10^{14} \text{ cm}^{-3}$. The carrier concentration in the p-region has a second-order effect compared with that of the n-region for the range of concentrations normally used.

Photocurrent and Quantum Efficiency

HgCdTe has a strong optical absorption coefficient and only thin layers are needed to produce high quantum efficiency. Typically in MW detectors the absorber need only be 4–5 μm thick and about twice this in LW detectors. Ideally the absorption should occur well within a diffusion length of the p–n junction to avoid signal loss due to recombination. A long carrier lifetime is nearly always observed in n-type material with low carrier concentration. Device engineers tend to favor using n-type absorbers for the best quantum efficiency and try to minimize the volume of the p-region for lower thermal leakage currents.

Excess Noise Sources in HgCdTe Diodes

There are many potential sources of excess noise in infrared detectors, and manufacturers strive to optimize obvious areas, such as the surface passivation (to limit surface leakage currents) and contacts. There are two other sources that have been reported in depth. The first

is linked to tunneling currents through traps, and the second is associated with crystal defects.

Many authors have reported an empirical relationship between tunneling leakage current and $1/f$ noise. The scatter within databases is usually large and the noise depends strongly on the technology used, but the noise trend is roughly given as αI_L^β , where α and β are variables depending on the device and leakage current mechanism. Leakage current from the trap-assisted tunneling mechanism results in β values close to 0.5, with α taking a value of $1 \times 10^6 \text{ A}^{0.5}$ [36.60]. With band-to-band processes the value of β moves towards 1. The nature of the trap has not been identified yet and it is not possible to exclude a variety of crystallographic defects. The physics of crystallographic defects in HgCdTe is complex because dislocations distort the local band structure and, via strain fields, the local bandgap, and this probably accounts for the variability in data in the literature.

The electrically active nature of dislocations and other crystal defects in HgCdTe is well reported [36.61, 62]. Dislocations can appear as n-type pipes and are associated with active defect centers. Many workers [36.63–68] have found that the reverse bias characteristics and $1/f$ noise of HgCdTe diodes depend strongly on the density of dislocations intercepting the junction. For HgCdTe this is an important observation because dislocations can easily be introduced during materials growth and the device fabrication process. Dislocations could increase the g–r current linearly in p-on-n heterostructures, along with a corresponding increase in $1/f$ noise current density [36.66]. Tunnel currents are also strongly associated with crystal defects, particularly at low temperatures.

The nature of defects in HgCdTe LW arrays has been studied in detail [36.58] in homojunction via-hole arrays (loophole arrays) made using high-quality LPE material, and a model has been proposed for the noise-generating mechanism. Threading dislocations that originate from the CdZnTe substrate and rise vertically through the layer can cause strong leakage in reverse bias if they intercept the junction, possibly because these dislocations can become randomly decorated during growth. Consequently, the threading dislocation density in the substrate is very important for controlling defect levels. Process-induced dislocations have a weaker effect on the junction properties resulting in an effective shunt resistance of about 40 M Ω , so an accumulation of this type of dislocation can result in a defect.

The current trend is to move towards lower temperature growth processes and growth on substrates with

poor lattice match, and this has refocused attention on grown-in dislocations. Many of these processes are not yet suitable for LW arrays. More data is needed for the VPE processes because the nature of the misfit dislocations and the geometry of the absorber will influence the magnitude of the excess noise.

36.6.4 Manufacturing Technology for HgCdTe Arrays

Considerable progress has been made over the last two decades in the epitaxial growth of HgCdTe. Bulk growth methods are still used to provide good quality material for photoconductor arrays, but for photovoltaic arrays there are problems associated with crystal grain boundaries, which are electrically active, and cause lines of defects. Also, there are limitations in the boule size, which makes it suitable for small arrays only.

Several epitaxial growth techniques are in use today. Manufacturers will select a technique that suits their device technology and the type of detectors they are trying to make. For instance, high-performance LW arrays will call for the best possible crystal quality, whereas large-area MW arrays can probably accept poorer material but must have large, uniform wafers. It is the aim of most manufacturers to produce high-quality layers in large areas at low cost, but this ideal has been elusive. At the present time the best structural quality material is grown using liquid phase epitaxy, LPE, onto lattice-matched crystals of CdZnTe, and this has been used successfully in homojunction technologies where the photosensitive junction is diffused into a homogenous monolith of material. There is a trend to move away from expensive CdZnTe substrates and both LPE and vapor-phase epitaxy (VPE) are now used on a variety of alternative substrates. Many groups favor VPE because the composition and doping profile can be easily controlled to produce complex devices, such as two-color detectors. The main HgCdTe growth processes are described here.

Summary of Growth

Using Liquid-Phase Epitaxy (LPE)

Liquid-phase epitaxy (LPE) of HgCdTe at present provides the lowest crystal defect levels, and very good short and long-range uniformity. LPE layers are grown using an isothermal supersaturation or programmed cooling technique or some combination. A detailed knowledge of the solid-liquid-vapor phase relation is essential to control the growth particularly in view of the high Hg

pressure. Challenges include: the compositional uniformity through the layer, the surface morphology, the incorporation of dopants and the specifications for thickness, wavelength, etc. A common component leading to high structural quality is the use of lattice-matched substrates of CdZnTe. These are grown by a horizontal Bridgman process and can supply layers as large as 6×4 cm. The CdZnTe substrates must be of the highest quality, and often this is a significant cost driver for the process.

Two different technical approaches are used: growth from a Hg-rich solution, and growth from a Te-rich solution. Advantages of the Hg-rich route include: excellent surface morphology, a low liquidus temperature, which makes cap layer growth more feasible, and the ease of incorporation of dopants. Also, large melts can provide for very good compositional and thickness uniformity in large layers and give consistent growth characteristics over a long period of time. Growth from Te-rich solutions can use three techniques to wipe the melt onto the substrate: dipping, tipping and sliding. Sliding boat uses small melt volumes and is very flexible for changing composition, thickness and doping. Tipping and dipping can be scaled up easily and can provide thick, uniform layers but the large melts limit flexibility. Double layers are also more difficult to grow.

Most manufacturers have taken their chosen growth system and tailored it to provide optimum material for their device technology. In particular the use of dopants and the deliberate introduction of compositional grades are very specific to the device structure. A crucial figure of merit however is the dislocation count, that controls the number of defects in 2-D arrays. Etch pit densities of $3\text{--}7 \times 10^4 \text{ cm}^{-2}$ are typically seen in the Te-rich sliding boat process reproducing, the substructure of the CdZnTe substrate [36.69]. The etch pits are associated with threading dislocations which appear to be normal or near normal to the layer surface. The substrate defect level can be as low as $\text{mid-}10^3 \text{ cm}^{-2}$ in some horizontal Bridgman CdZnTe, but this is not easy to reproduce. Similar defect densities are found in CdTeSe material but the impurity levels have proved difficult to control in the past. Device processing therefore must expect to cope with defect levels in the $\text{mid-}10^4 \text{ cm}^{-2}$ range for routine CdHgTe epilayers, and this will set the ultimate limit on the number of defects in HgCdTe 2-D arrays. Several groups have used the LPE process on low-cost substrates, including: CdZnTe or CdTe on GaAs/Si wafers [36.70] or the PACE technology on sapphire described in detail in Sect. 36.6.4.

Summary of Growth Using Metalorganic Vapor-Phase Epitaxy (MOVPE)

A detailed summary of the state of the art for MOVPE technology has been produced [36.71], but this section summarizes the main points.

MOVPE growth depends on transporting the elements Cd and Te (and dopants In and As) at room temperature as volatile organometallics. They react along with Hg vapor in the hot gas stream above the substrate or catalytically on the substrate surface. The drive to lower temperatures and hence lower Hg equilibrium pressures has resulted in the adoption of the Te precursor di-isopropyl telluride, which is used for growth in the 350–400 °C range. A key step in the success of this process is to separate the CdTe and HgTe growth so that they can be independently optimized. This is called the IMP process (interdiffused multilayer process) [36.72]. IMP results in a stack of alternating CdTe and HgTe layers and relies on the fast interdiffusion coefficients in the pseudobinary to homogenize the structure at the growth temperature. Doping is straightforward using Group III metals (acceptors) and Group VII halogens (donors). For instance, ethyl iodide is used for iodine doping.

The main morphological problem for MOVPE are macro defects called hillocks, which are caused by preferred 111 growth, nucleated from a particle or polishing defect. Hillocks can cause clusters of defects in arrays. Orientations 3–4° off 100 are used primarily to reduce both the size and density of hillocks.

A variety of device structures with layers have been reported [36.73] based on MOVPE-grown HgCdTe layers on 75 mm-diameter GaAs on silicon.

Summary of Growth Using Molecular Beam Epitaxy (MBE)

A good detailed summary of the state of the art for MBE technology has been reported [36.74].

MBE offers the lowest temperature growth under an ultrahigh vacuum environment, and, in common with MOVPE, in situ doping and control of the composition and interfacial profiles. These are essential for the growth of advanced and novel device structures. Typically growth is carried out at 180–190 °C on 211 CdZnTe substrates. Effusion cells of CdTe, Te and Hg are commonly used. Hg is incorporated into the film only by reacting with free Te, and so the composition depends on the Te to CdTe flux ratio. The structural perfection depends strongly on the Hg to Te flux ratio and growth is usually restricted to a tight temperature range. Indium is the most widely used n-dopant and is well activated. p-type dopants are less conveniently incorpo-

rated in situ but manufacturers have devised a number of processes to force As onto the proper Te site. Again the Hg to Te ratio and growth temperature is crucial to achieving good activation. In general, reproducibility seems more difficult to achieve than MOVPE. MBE structural problems center mainly on pinholes or voids. Some very good EPD levels have been reported, but in general the EPD levels are an order or more higher than the best quality LPE.

Junction Forming Techniques

For n–p devices, crystal growers can obtain the desired p-type level by controlling the density of acceptor-like mercury vacancies within a carrier concentration range of, say, 10^{16} to 10^{17} cm⁻³. Neutralizing the Hg vacancies and relying on a background level of donors to give the n-type conversion creates the photodiode junctions. Mercury can be introduced by thermal diffusion from a variety of sources, but high-temperature processes are not very compatible with HgCdTe at the device level. However, type-conversion can be readily achieved by processes such as ion beam milling [36.75] and ion implantation [36.76–81]. Type conversion can also be achieved using plasma-enhanced milling in the VIAP process [36.81] and also using H₂/CH₄ plasmas [36.82]. The common feature is that the conversion depth is much deeper than would be expected from the implantation range alone.

The current knowledge on type conversion using ion beam milling is described by [36.58] and the current knowledge for ion implantation is summarized by [36.83]. The explanation for the behavior of HgCdTe under ion beam bombardment involves a number of physical mechanisms. Firstly, the low binding energies, ionic bond nature and open lattice of HgCdTe encourages the liberation of free mercury at the surface and subsequent injection by the ion beam. The injection mechanism probably involves a recoil implantation process. Once the Hg interstitial is injected, the mobility is apparently extremely high and there is some evidence that this is stimulated by the ion beam in a process related to the anomalously high diffusion rates of impurities often observed in SIMS analysis. Another factor is the movement of dislocations under the influence of the ion beam and possibly stimulated by strain fields. A number of workers report that the n-type carrier concentration in the converted region is very low, and in fact fast-diffusing impurities such as the Group IB elements Cu, Ag and Au and the Group IA elements Na, K and Li, which reside on the metal sublattice, are swept out of the n⁻ region of the diode by the flux of Hg interstitials. This impurity

sweep-out effect is serendipitous because it means that in ion beam generated junctions the n-regions are very pure, free of S-R centers and have weak doping, creating an ideal structure for high-performance detectors. The detailed atomic level processes taking place including the role of mercury interstitials, dislocations and ion bombardment in the junction-forming process are complex and not well-understood in detail. Despite the complex physics involved, manufacturers have achieved good phenomenological control of the junction depth and n-dopant profiles with a variety of processes.

Via-Hole Technologies

Via-hole devices share many of the process stages of photoconductive arrays and have been commercially produced since 1980. Arrays made using this process are known as loophole devices [36.84] and HDVIPTM devices [36.81]. By using a thin monolith of HgCdTe bonded rigidly to the silicon, the thermal expansion mismatch problem is overcome because the strain is taken up elastically. This makes the devices mechanically and electrically very robust and suitable for very long linear arrays, such as a 512×2 array of over 16 mm in length [36.69].

The process flow of the via-hole device using LPE material is illustrated in Fig. 36.12 [36.59, 69]. The process has two simple masking stages. The first defines a photoresist film with a matrix of holes of, say, 5 μm

diameter. Using ion beam milling, the HgCdTe is eroded away in the holes until the contact pads are exposed. The holes are then backfilled with a conductor, to form the bridge between the walls of the hole and the underlying metal pad. The junction is formed around the hole during the ion beam milling process, as described in Sect. 36.6.4. The second masking stage enables the p-side contact to be applied around the array. Figure 36.12 shows a photomicrograph of one corner of the hybrid, illustrating the membrane-like nature of the HgCdTe on the silicon. The device structure inherently produces low crosstalk in small pixels.

The HDVIPTM process [36.81] results in a similar structure but uses a plasma etching stage to cut the via-hole and an ion implantation stage to create a stable junction and damage region near the contact. In order to achieve higher lifetimes and lower thermal currents, Cu is introduced at the LPE growth stage. This is swept out during the diode formation and resides selectively in the p-region, partially neutralizing the S-R centers associated with Hg vacancies and achieving dark currents approaching those of fully doped heterostructures.

In via-hole processes the cylindrical shape of the junction minimizes the intersection with threading dislocations (Sect. 36.6.3). This has been demonstrated by the difference in yields when the HDVIPTM device is extended by a planar junction [36.81].

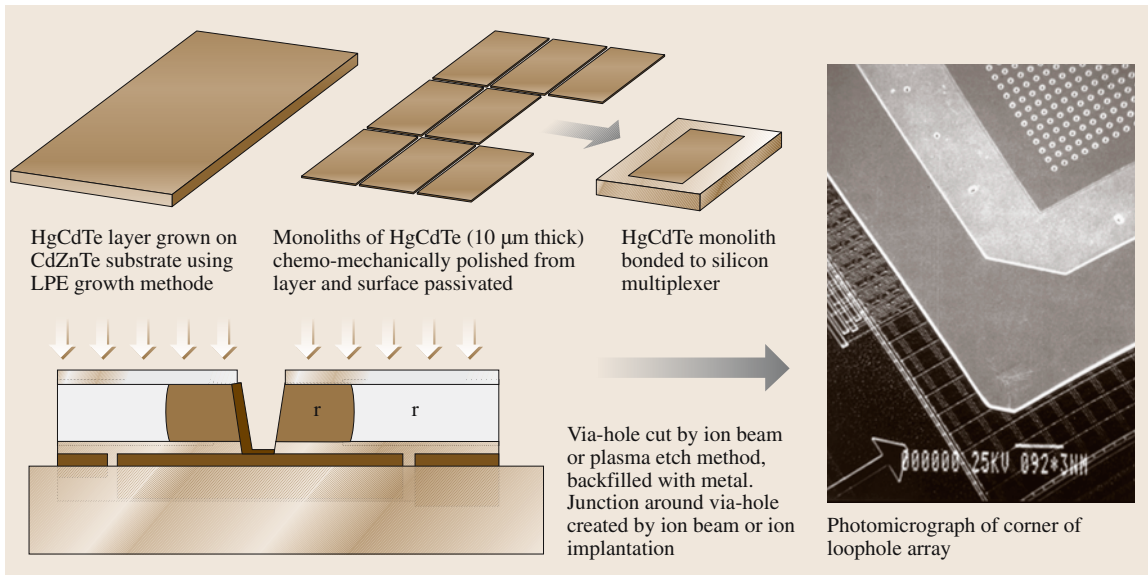

Fig. 36.12 Processing of HgCdTe arrays using LPE material and via-hole technology

Planar Device Structures Using LPE

The planar device structure illustrated in Fig. 36.13 is the simplest device structure currently used. It is consistent with a number of junction forming processes, e.g. ion implantation, diffusion and ion milling. The matrix of junctions is mass connected to an underlying silicon multiplexer using indium bumps. The strength of the process is the simplicity and the compatibility with epitaxially grown materials. A process based on high-quality LPE material and ion-implanted junctions is conducive to good-quality detectors and volume production [36.85]. In the simplest form, the process needs three masking stages for the junction and pixel contact, and one for the contact to the p-side. The device is backside-illuminated, i.e. it is illuminated through the substrate, and so this must be of high optical quality. Careful control of the junction geometry is needed to avoid crosstalk due to the diffusion of minority carriers into adjacent pixels, especially in the case of small pixel sizes. The thermal expansion mismatch between the HgCdTe/CdZnTe substrate combination and the silicon multiplexer is another important consideration in this device structure and this can restrict the practical size of the array unless the CdZnTe substrate is thinned.

Double Layer Heterojunction Devices (DLHJ)

Thermal leakage currents in HgCdTe devices tend to arise from the p-type side, and most advanced technologies strive to improve the operating temperature by using the n-type side as the absorber. n-type HgCdTe is easier to control at low carrier concentrations and is relatively free of Schottky-Read centers that limit the lifetime in p-type material. The p-type side then is often minimized

in volume or uses a wider bandgap to reduce the thermal generation. For heterostructures that are grown in situ, it is necessary to completely isolate the junction, forming a so-called mesa device. This is usually performed using a chemical etch because of the electrical side effects of using dry processing techniques.

When a device uses different compositions or doping levels, a nomenclature is adopted to describe the structure. The definition used in this chapter is as follows. An n-type diode formed in a p-type layer is described as an n-p device, so the first letter is the layer nearest the contact and photons are absorbed in the p-type layer. Wider bandgap material is indicated by using a capital letter. A superscript “-” or “+” denotes particularly low or high doping.

Double-layer heterojunction devices have been developed mainly in the US for long-wavelength detectors with low thermal leakage currents (or high R_0A values). A number of elegant device structures have been reported with R_0A values that are an order of magnitude higher than those of via-hole or planar diodes. The back-illuminated mesa P^+-n heterojunction, illustrated in Fig. 36.14, is a widely used device, and has been reported from both LPE and MBE material. This structure makes good use of the n-type absorber to give a high fill factor. Devices have been made using a vertical dipper LPE process from a Hg rich solution [36.86] and using a horizontal slider LPE process from a Te-rich solution [36.87–89]. The p-type layer is doped with arsenic to around $1-4 \times 10^{17} \text{ cm}^{-3}$ and is grown by the vertical dipper LPE process from a Hg-rich solution. An n^-P^+ structure has been reportedly grown from MBE which has the advantage of very low crosstalk because of the complete electrical isolation of the absorber [36.90].

Fig. 36.13 Schematic of planar indium-bumped hybrid

Fig. 36.14 Schematic of double-layer heterojunction (DLHJ)

Fig. 36.15 Schematic of double-layer planar heterostructure (DLPH)

Other workers have produced the conventional P^+n^- structure using an MBE process [36.91].

Mesa heterostructures have a technologically difficult passivation stage on the sidewalls of the mesa, which can lead to reverse bias leakage and uniformity problems if not optimum. In order to solve the sidewall problem, a clever diffused heterostructure has been reported [36.92], called a double-layer planar heterostructure (DLPH). This is a back-illuminated arsenic-implanted p-n-N planar buried junction structure [36.93], as illustrated in Fig. 36.15. The junction is formed by arsenic implantation into a three-layer N-n-N film grown in situ by MBE onto a CdZnTe substrate. The unique feature of this structure is that the junction is buried beneath the top wide-bandgap n-type layer. The junction intercepts the surface in wider gap CMT, thereby reducing the generation rates for any surface defects that may be present. The arsenic doped region must extend deep enough into the narrow gap absorber layer in order to collect photocarriers. This necessitates that the wide gap layer be thin (on the order of $0.5\ \mu\text{m}$) and that the compositional interdiffusion between the wide gap and absorber be minimal. Growth by MBE at low temperature (175°C) satisfies these requirements. Another feature of this structure is the wide-gap n-type buffer layer between the absorber and the substrate. This buffer layer keeps carriers that are photogenerated in the absorber away from the film-substrate interface where there can be interface recombination. The DLPH process has been used to produce arrays of up to 1024×1024 on $18.5\ \mu\text{m}$ pitch (HAWAII multiplexers) with high quantum efficiency [36.94].

Wafer-Scale Processes Using Vapor Phase Epitaxy on Low-Cost Substrates

There is a dual purpose in developing vapor phase epitaxy technologies. Firstly, it opens up the possibility of growing complex multilayer materials for a whole range of new device structures, and secondly it allows growth on lower cost substrates. Certainly the elegance of this technique is that the composition, thicknesses and doping levels can be programmed, in principle, to grow any required detector structure. For instance, multilayer, fully doped heterostructures have been grown which demonstrate low thermal leakage current by a process called Auger exclusion [36.95]. Also, two-color detector structures can be grown as described in Sect. 36.6.8. The main commercial drive though is to cost-reduce the manufacture of large-area arrays and avoid expensive CdZnTe substrates. Silicon, gallium arsenide and sapphire are the commonest substrates used because they are available commercially in large-area wafers at relatively low cost. Figure 36.16 illustrates a typical process flow.

One of the main considerations when designing large arrays is the thermal mismatch problem between the various layers in the device and carrier, which can cause

Fig. 36.16 Wafer-scale processing using VPE HgCdTe material, mesa diodes and indium bump interconnect technology

bowing or cracking at low temperature. The silicon multiplexer has a very low thermal expansion coefficient compared to most materials used and a number of different techniques are used to cope with this.

Some groups focus on the growth of HgCdTe on silicon substrates so that, when bump-bonded, the substrate and multiplexer are balanced. Silicon is also mechanically strong, available in large wafers at low cost, and avoids the recurring problem of impurity out-diffusion in CdZnTe substrates. A 75 mm-diameter silicon wafer can produce about twelve 640×512 arrays. For HgCdTe there is a 19% lattice constant mismatch with silicon, and this can potentially provide high levels of misfit dislocations, resulting in degraded performance, particularly at longer cut-off wavelengths. However at short and medium wavelengths the effect of misfit dislocations is reduced enough to make these wafer-scale processes viable at the present time. Most of the MOVPE work on silicon has used a GaAs layer to buffer the lattice mismatch between silicon and HgCdTe [36.73], and a variety of device structures are reported using MOVPE layers grown on 75 mm-diameter GaAs on silicon layers. MBE growth on silicon substrates of 100 mm in diameter has been used to grow MW HgCdTe layers [36.96]. The MBE work has used buffer layers of CdZnTe and CdTe to minimize the density of misfit dislocations. Both MBE and MOVPE growth has been used to produce LW arrays on misorientated silicon substrates [36.97]. An MBE CdTe/ZnTe layer is first grown and this acts as a buffer for the HgCdTe growth using an MOVPE process.

Another approach, known as PACE, has been described [36.98]. The process uses a 75 mm-diameter substrate of highly polished sapphire, which remains

with the device throughout. The thermal expansion problem is overcome by using a carrier substrate of sapphire so that the silicon multiplexer is sandwiched in the middle. The process starts with a buffer layer of CdTe deposited using an organometallic vapor-phase epitaxy (OMVPE) process to $8.5 \mu\text{m}$ thickness followed by a $10 \mu\text{m}$ -thick p-type HgCdTe layer grown by LPE. The n-p diodes are formed by ion implantation. This process has been used to fabricate 1024×1024 arrays with $3.2 \mu\text{m}$ cut-off [36.42] and 2048×2048 SW arrays of 16 cm^2 in area [36.99]. The 2048×2048 array, produced by Rockwell Scientific Company LLC for an astronomy application, is shown in Fig. 36.17. The arrays are $37 \times 37 \text{ mm}$ in size and are backside-illuminated through the sapphire substrate.

36.6.5 HgCdTe 2-D Arrays for the 3–5 μm (MW) Band

In the MW band, the development of array technology has reached a stage where all of the reported device processes will result in essentially background-limited performance for a wide range of applications. Individual arrays differ from one another in array size and pixel size and in imaging artefacts, such as uniformity, crosstalk and blooming. Some mention needs to be made of the factors controlling sensitivity in 2-D arrays, because this does not depend primarily on the HgCdTe but the silicon multiplexer.

Both charge-coupled devices (CCDs) and standard foundry CMOS devices have been used for multiplexing infrared 2-D arrays, but CMOS is now the preferred choice and CMOS circuits will operate well at low temperatures. The function of the multiplexer is to integrate the photocurrent from the photodiode array, perform a limited amount of signal processing and sequentially readout the signals. Most manufacturers produce their own multiplexer designs because these often have to be tailored to the application. For background-limited detectors, the NETD (noise-equivalent temperature difference) can be shown to be inversely proportional to the square root of the number of integrated photogenerated electrons [36.100]. High sensitivity can therefore only be achieved if a large number of electrons are integrated and this requires the integration capacitance in each pixel to be fairly high. Normally the capacitor is created using a MOSFET structure with a thin gate oxide dielectric and capacitance densities as high as $3 \text{ fF } \mu\text{m}^2$ are typical. Nevertheless, the capacitance is restricted to about 1 pF in pixels of around $25 \mu\text{m}$ square, and so the best NETD that can be expected is about 10 mK per

Fig. 36.17 2048×2048 SW array for astronomy. (Courtesy of Rockwell Scientific Company)

frame. It is important to note that this NETD limitation has nothing to do with the HgCdTe but only depends on the multiplexer design. Furthermore, as the pixel size is reduced the capacitance is decreased disproportionately, so the NETD cannot be maintained in small-pitch arrays.

Some general comments about operating temperature can be made. Standard vacancy-doped HgCdTe diodes, such as planar or via-hole homojunctions, need cooling to 120–140 K for BLIP performance in typical thermal imaging applications. The standard HDVIPTM, which is extrinsically doped with many fewer vacancies, can operate up to 155 K. HgCdTe diodes fabricated with controlled doping and bandgap engineering can achieve BLIP operation near to ≈ 200 K. Operating at a higher temperature can prolong the life of cryocoolers and results in lower power consumption.

HgCdTe offers better spatial resolution (often quantified as the modulation transfer function, MTF) than some competing technologies such as planar InSb processes. Fully defined MOVPE or MBE diode structures will have the best MTF performance, but via-hole technologies (loophole and HDVIP) closely approach them because of their concentric junction shape, and this permits true resolution improvement in small pixels. DLHJ structures and planar structures rely on lateral collection to give very high fill factor, and high quantum efficiencies, and they need to have restricted sideways diffusion to limit blurring. Blooming due to an intense optical highlight follows a similar argument.

36.6.6 HgCdTe 2-D Arrays for the 8–12 μm (LW) Band

LW HgCdTe detectors were originally developed for long linear arrays and the processes can be extended to 2-D arrays with one additional consideration. The earth plane of the array must carry the sum of the photocurrent from all of the pixels in the array, and if there is insufficient conductance a voltage will appear between the center and edge of the array. This is called “substrate debiasing”, and in the extreme case will inhibit injection in the center diodes. In any event it provides a potential long-range crosstalk mechanism and detector designers will try to minimize the resistance of the earth plane layer. In homojunction arrays, the p-type common layer cannot be doped high enough and a special metal grid is needed, as shown in the DRS Technologies array in Fig. 36.18. In other technologies the common layer must be doped high enough to prevent long-range crosstalk and use junctions with high dynamic resistance.

Fig. 36.18 LW HDVIP array with metal grid for substrate debiasing control. (Courtesy DRS Technologies)

36.6.7 HgCdTe 2-D Arrays for the 1–3 μm (SW) Band

Important applications in the SW (1–3 μm) wave-band include: thermal imaging (using nightglow), spectroscopy and active imaging using lasers. Other materials can be used for SW detectors but products such as InGaAs tend to have high noise beyond 1.7 μm due to defects arising from the lattice mismatch with the InP substrate. Most HgCdTe technologies can be extended to SW with little change to the processing. Carrier lifetimes should be dominated by radiative recombination, but in fact S-R centers and technologically related limits probably apply in practice. SW detectors can produce good quality diodes in the presence of fairly high levels of misfit dislocations and so can be made using some of the newer technologies described in Sect. 36.6.4. For imaging and spectroscopy applications, typical operating temperatures are around 200 K and thermoelectric coolers are often offered as standard products.

A growing area is active imaging using eyesafe 1.54 μm lasers. The shorter wavelength results in higher resolution for a given optical aperture size and is particularly beneficial in long-range sensor systems. The very short pulse nature of the laser can be used to give range information and is often used with gated detectors to produce imaging in a certain range zone (so-called laser shape profiling). When range information is produced it is called laser range profiling and, in the limit, 3-D imaging. At present the field is in its early development stage and workers are using relatively small arrays to perform initial research. Detectors for this field need to be very fast and use a wide, weakly doped absorber

region to give low capacitance. This is a so-called PiN diode, where the “i” stands for intrinsic. It also needs a very low series resistance to withstand the shock of the laser return, and this lends itself to metal grids and heavily doped heterostructures.

In most SW applications the photon flux is low and it is difficult to achieve reasonable signal-to-noise performance. However, it is relatively easy to enhance the signal by providing some avalanche gain in the device. Electron avalanching in MW HgCdTe via-hole diodes has been described [36.101, 102]. The electron and hole ionization rates are very different in HgCdTe, and this allows almost pure exponential, noise-free avalanche gain at fairly moderate voltages. So avalanche gain can readily be achieved for wavelengths above about $2.5\text{ }\mu\text{m}$ when the absorber region is p-type and electrons are the minority carriers. A gain of 10 is typically observed for around 5 V at a cut-off of $5\text{ }\mu\text{m}$. An alternative structure uses SW material ($1.6\text{ }\mu\text{m}$) and a resonant enhancement of the hole impact ionization rate when the bandgap equals the spin-orbit split-off energy [36.103]. Gains of 30–40 have been seen with voltages of 85–90 V.

SW laser-gated imaging systems using avalanche gain in HgCdTe are now being reported for use in long-range identification applications [36.104]. Here the combination of sophisticated ROICs and high quality HgCdTe device processing is producing 320×256 arrays with a sensitivity down to 10 photons rms.

36.6.8 Towards “GEN III Detectors”

“GEN III” is a commonly used term which stems from the abbreviation for third-generation infrared detector. The definition of a “GEN III” detector can differ between different nations but the general guideline is any detector that offers an imaging advantage over conventional first- and second-generation systems. Common agreed examples include megapixel arrays with high density, dual color or even multispectral arrays, higher operating temperature, fast readout rates, very low NETD due to pixel-level signal compression and retina-level signal processing. Some of the progress made in such research is described here in more detail.

Two-Color Array Technology

Resolving the spectral signature can enhance the identification of objects in a thermal image. As a stepping stone to true multispectral arrays, many manufacturers are developing two-color detectors with simultaneous readout of flux levels in two separate infrared bands. A good example of a field requirement is to separate

a sun glint from a hot thermally emitting object. The field is still in its early development stages, but some good results have been achieved.

Two-color arrays use two layers of HgCdTe with the longer wavelength layer underneath. The technological challenge is to make contact with the top layer without obstructing the sensitive area of the bottom layer. Ideal devices, where the integration takes place simultaneously and the sensitive area is co-spatial, are practically difficult to make on normal pixel sizes of say less than $50\text{ }\mu\text{m}$. Most dual-color devices using indium bumps need two contacts within each pixel and make contact to the top diode by etching a hole in the bottom layer. The silicon needs to be custom-designed because the flux levels in the two bands may be markedly different. The polarity of the input MOSFET and the gain within the silicon must be matched to the technology and application.

Several successful arrays have been reported including a 64×64 simultaneous MW/LW dual-band HgCdTe array on $75\text{ }\mu\text{m}$ pitch [36.105]. The array is fabricated from a four-layer P-n-N-P film grown in situ by MOVPE on CdZnTe and mounted on a custom ROIC. This approach has been applied to the double-layer planar heterostructure, DLPH, in a process called SUMIT, which stands for simultaneous unipolar multispectral integrated technology [36.106]. The DLPH structure can be turned into a two-color device by employing two absorbers with different bandgaps separated by a wide bandgap barrier. An etch step is used to expose the lower, shorter wavelength absorber and to form an arsenic doped junction. A pixel size of $40\text{ }\mu\text{m}$ for each color is used in 128×128 demonstrators for MW/MW arrays. A variant of this basic process has also been presented by AIM [36.107] and they have achieved two colors in a concentric arrangement in 192×192 and 256×256 arrays with $56\text{ }\mu\text{m}$ pitch, again using a full custom ROIC.

Two-color arrays have been fabricated using a via-hole type structure in which each pixel has two via-holes [36.81]. One is for connecting the longer wavelength array to the silicon in the normal way and the other is isolated from the longer wavelength material and connects the shorter wavelength to the silicon, as is illustrated schematically in Fig. 36.19. The spectral response of the two colors is shown in Fig. 36.20 for the two different doublets. The two-color arrays utilize standard 640×480 , $25\text{ }\mu\text{m}$ pitch ROICs (as used in LW focal plane arrays). The unit cell design in these ROICs incorporates one buffer amplifier circuit for every two HgCdTe pixels. The two-color array actually uses four

Fig. 36.19 MW/LW HDVIP FPA two-color composite. (Courtesy DRS Technologies)

Fig. 36.20 Spectral response of MW/MW two-color HDVIP HgCdTe FPA. (Courtesy DRS Technologies)

mono-color pixels to form a two-color unit cell, thus resulting in a $50\text{ }\mu\text{m} \times 50\text{ }\mu\text{m}$ geometry, with two buffer amplifiers per unit cell, one for each color.

The shrink potential of dual-color technologies is limited by the need for two contacts per pixel. An alternative approach is to use a so-called bias-selectable detector [36.108–110], which needs only one bump and is compatible with small pixel sizes. This is an elegant technique but has the operational disadvantage of nonsimultaneous integration, and for this reason these detectors are often called sequential mode, dual-band detectors. Typical devices use a p-n-N-P or n-p-P-N sandwich structure with each p-n junction in different composition material. The wavelength can be selected by the bias polarity. There is a potential problem with parasitic transistor action and this needs to be suppressed

by appropriate barriers. The silicon circuit requires a PMOS input for one polarity and an NMOS for the other and these must be switched for each color.

Higher Operating Temperature (HOT) Device Structures

The general principles for designing HOT HgCdTe detectors have been proposed over the past two decades, primarily as a result of research in the UK. Good summaries have been reported in [36.111, 112]. The advantages afforded by HOT detectors are in the area of cost of ownership and portability. LW arrays operating at only a few tens of degrees higher can significantly improve the mean time before failure (mtbf) of a Stirling engine cooler. In the MW band BLIP detectors on thermoelectric coolers could offer a much cheaper, smaller and more robust product, ideally suited to continuously operating security-type applications. Operation at 220 K has been demonstrated for a 128×128 array using MOVPE heterodiode technology [36.113], and the key step was designing a multiplexer that enabled very accurate biasing of the diodes at zero volts to suppress the dark current and associated $1/f$ noise.

The possibility of operating detectors at temperatures near room temperature has been proposed [36.114]. The basic structure is a P-p⁻N, as illustrated in Fig. 36.21. The active volume of the absorber is small relative to a minority carrier diffusion length, and it is operated in strong nonequilibrium by reverse biasing the minority carrier contact to completely extract all of the intrinsically generated minority carriers. To preserve space-charge neutrality, the majority carrier concentration drops to the background dopant concentration and Auger generation is effectively suppressed. Remaining components are associated with S-R centers and possibly injection from the contact and surface regions. The realization of HOT LW arrays will depend on the suppression of high $1/f$ noise associated with the reverse bias operation. In MW arrays it is also important to

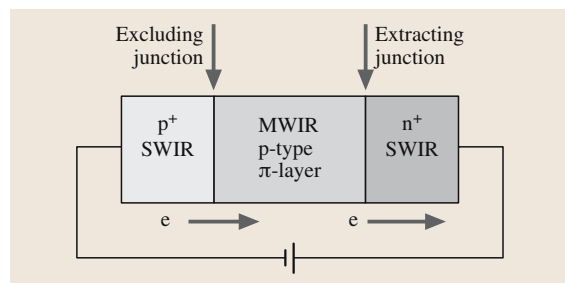

Fig. 36.21 Schematic of HOT device structure

suppress competing recombination mechanisms. Nevertheless, the device concept has enormous importance as a route towards high-performance infrared detectors with minimal cooling.

Retina-Level Processing

In very large arrays operating at high frame rates, the downloading of signal data and the subsequent signal processing can be daunting and is called the data processing bottleneck problem. The human retina presents an example of how evolution has dealt with the problem. The eye performs a number of image processing operations in the “z-plane”, including, in order: logarithmic photon sensing, spatial filtering, temporal filtering, motion sensitivity and data decomposition. An essential function is the Difference of Gaussian or DoG filter which is used for both edge and contrast enhancement [36.115].

Focal plane arrays with neuromorphic processing are under development at a number of centers [36.116–118]. A good example is the MIRIADS programme (miniature infrared imaging applications development system). MIRIADS uses a neuromorphic FPA, with temporal high-pass filtering, frame co-adding and a Difference of Gaussians operation to detect motion, enhance edges and reject ambient light levels. The current reported array is a 64×64 .

36.6.9 Conclusions and Future Trends for Photovoltaic HgCdTe Arrays

Photovoltaic 2-D HgCdTe detectors are serving many applications worldwide and are supplanting photoconductive detectors in second-generation systems for military, commercial and scientific applications, offering improved temperature sensitivity, lower power consumption, weight and volume. The continuing development work within manufacturing centers, supported

by the wider scientific community, is aimed at increasing the radiometric performance, reducing defects and reducing manufacturing costs. Medium-term research is being directed at the best advanced materials and device structures for the next generation of HgCdTe arrays, which will combine state of the art background limited performance with low-cost wafer-scale processing. In the future it is envisaged that HgCdTe detectors will be grown directly on silicon or even silicon multiplexers for very low cost detectors. Bandgap engineering will produce heterostructure detectors with much higher operating temperatures. This will enable background-limited operation in MW arrays at near room temperature and operation of LW detectors on thermoelectric coolers or low-power Stirling engines. Device structures will be extended to produce bispectral and multispectral capability. Advanced detectors will critically depend on the future development of multiplexers. Challenges for the future include: arrays with larger physical size, smaller pixels, higher sensitivity, faster frame rate and even perhaps retina-type processing to reduce the need for external signal processing. The ultimate performance potential of HgCdTe will ensure that it is the material of choice for all high-performance infrared systems. In MW arrays it will compete with InSb offering better imaging characteristics and higher operating temperature. Active imaging will drive a major growth in SW array technology. The top performing thermal imaging cameras currently depend on LW, HgCdTe, long linear arrays offering high-definition TV images: the only technology currently capable of doing this economically. The market for smaller LW 2-D arrays is dominated by uncooled (thermal) detectors and multiple quantum well detectors, but HgCdTe offers considerably improved sensitivity, and once the cost becomes competitive it should compete with these technologies for many applications.

36.7 Emission Devices in II–VI Semiconductors

Infrared emission devices, in the form of LEDs (light emitting diodes) and laser diodes, are used in a broad range of applications such as gas sensors, infrared scene simulators, molecular spectroscopy, free space communications, fiber optic communications and LIDAR (light detection and ranging). A useful summary of emission device theory and current progress has been presented by [36.119]. There is competition from lead salt semiconductors (in the 3 to $34\text{ }\mu\text{m}$ range) and narrow gap

III–V compounds. HgCdTe LEDs use a forward-biased junction to inject minority carriers into an n-type region, typically with low doping to encourage radiative recombination. The external photon efficiency is limited by factors such as competing recombination mechanisms, reabsorption of the photons and internal reflection. Nevertheless, efficiencies as high as 5% have been achieved at $4\text{ }\mu\text{m}$, using an immersion lens to overcome internal reflection [36.120].

One of the disadvantages of the LED is that the spectrum is often too broad for many applications, and lasers are needed. Lasers also offer greater output power and higher spatial coherence, but they are more difficult to make and have additional noise mechanisms. Infrared lasers covering the 3–5 μm band have been demonstrated with pulsed operation at 80 K. It is only recently that the complex double heterojunction structures needed for lasing have been available from low-temperature VPE processes, so the field is relatively young. Nevertheless, peak powers of up to several milliwatts have been recorded in diode pumped lasers and over 1 W in optically pumped lasers.

Using a structure similar to that reported in Sect. 36.6.8 and illustrated in Fig. 36.21, the carrier densities, in reverse bias, can be lowered to well below the thermal equilibrium values. Under this condition, the absorption of photons can exceed the emission rate and the surface of the device can look cold. This is called negative luminescence [36.121] and devices have been developed for use as temperature references in thermal imaging cameras.

Infrared LEDs have also been reported [36.122] in the dilute magnetic semiconductors $\text{Hg}_{1-x}\text{Mn}_x\text{Te}$ and $\text{Hg}_{1-x-y}\text{Cd}_x\text{Mn}_y\text{Te}$, where, in principle, the bandgap could be tuned by the applied magnetic field.

36.8 Potential for Reduced-Dimensionality HgTe–CdTe

The emergence of low-temperature growth processes will enable HgTe–CdTe structures to be grown with dimensions small enough to show quantum confinement effects. At present this research is in its early stages, and there are no active programs to make devices, but this could change in future. HgTe–CdTe superlattices offer many benefits for detectors. The minority carrier lifetime could be enhanced beyond that of bulk material, providing better quantum efficiency. The optical absorption coefficient can be much larger than bulk material, allowing LW detectors to use absorbers as thin as

a few microns. Furthermore, tunneling currents can be reduced by orders of magnitude, permitting operation at much longer wavelengths. The state of the art of reduced dimensionality material is summarized in [36.123].

Quantum well lasers are also known to offer significant advantages over double heterojunction devices with bulk active regions. For instance, the maximum operating temperatures for pulsed and CW lasers could be increased by over 100 K, and this would have important consequences for the attractiveness of narrow-gap II–VI emitters.

Optoelectronic

37. Optoelectronic Devices and Materials

Unlike the majority of electronic devices, which are silicon based, optoelectronic devices are predominantly made using III–V semiconductor compounds such as GaAs, InP, GaN and GaSb and their alloys due to their direct band gap. Understanding the properties of these materials has been of vital importance in the development of optoelectronic devices. Since the first demonstration of a semiconductor laser in the early 1960s, optoelectronic devices have been produced in their millions, pervading our everyday lives in communications, computing, entertainment, lighting and medicine. It is perhaps their use in optical-fibre communications that has had the greatest impact on humankind, enabling high-quality and inexpensive voice and data transmission across the globe. Optical communications spawned a number of developments in optoelectronics, leading to devices such as vertical-cavity surface-emitting lasers, semiconductor optical amplifiers, optical modulators and avalanche photodiodes. In this chapter we discuss the underlying theory of operation of the most important optoelectronic devices. The influence of carrier–photon interactions is discussed in the context of producing efficient emitters and detectors. Finally we discuss how the semiconductor band structure can be manipulated to enhance device properties using quantum confinement and strain effects, and how the addition of dilute amounts of elements such as nitrogen is having a profound effect on the next generation of optoelectronic devices.

37.1 Introduction to Optoelectronic Devices

In this chapter we introduce the underlying theory and operating principles of semiconductor optoelectronic devices. There exist today a plethora of optoelectronic devices, which are used in a multitude of applications. These devices include sources such as light-emitting diodes (LEDs) and laser diodes, photodetectors, optical amplifiers and optical modulators. With such devices, one can generate, modulate, detect and switch photons in an analogous way to electrons in an electrical circuit. We begin this chapter by considering the underlying physical interactions between electrons and photons that occur in semiconductors and how they may be harnessed to produce a wide variety of devices. At the time of writing, optoelectronic devices have found their way into many different aspects of modern life whether it be the ubiquitous indicator LEDs on hi-fi systems, televisions, computers, solid-state lighting and countless other items or in the bar-code scanning systems at the supermarket, the compact disc (CD) player, CD-ROM/CD±R/CD±RW or digital versatile disk (DVD), DVD-ROM/DVD±R/DVD±RW/DVD-RAM at home, the laser printer in the office, or when using a telephone or watching cable television. Over the past decade or so there has been an information explosion whereby information from all over the world can be quickly accessed by anyone equipped with a computer and access to the internet. In all of these applications it is a semiconductor-based optoelectronic device that forms an essential part of the system.

One of the major advantages of semiconductor devices is their small size. For example, a typical edge-emitting laser measures approximately 500 μm long by 250 μm wide with a thickness of 100 μm . Several thousand such devices can be made from a single wafer. Thus, even when packaged, these form very compact sources of coherent radiation. Other types of laser, such as the gas laser, simply cannot compare with the semiconductor laser in terms of size, modulation rates, flexibility of application and power consumption. Furthermore, semiconductor devices can be tailored to meet the exacting requirements of an application by simply altering the composition of the various layers forming the structure.

Of the uses of semiconductor devices outlined above, their use in telecommunications stands out as having the largest impact on modern life. Digital-based data transmission allows information to be transmitted over large distances with a much lower degradation in signal quality compared with older, analogue-based

systems. Optical telecommunications are ideal for use in digital systems, enabling data transmission rates in excess of 10 Gbit/s using short optical pulses of < 100 ps in duration. Even at this exceptionally fast rate of data transmission, bit error rates of better than 1 in every 10^9 bits can be achieved. Such capabilities are a direct consequence of significant research and development work that has gone into producing semiconductor devices for the emission and detection of light. In the next section, we give a brief history of this development before proceeding to discuss the key elements of physics and technology related to the device operation.

37.1.1 Historical Perspective

The development of optoelectronic devices began in the early 1960s with the development of the light-emitting diode and soon thereafter, the semiconductor laser. *Holonyak* had been experimenting with the alloy GaAsP to produce visible light via spontaneous emission and was successful in producing visible (red) light-emitting diodes [37.1]. Stimulated emission was first predicted by *Albert Einstein* in his famous 1917 paper, *Zur Quantentheorie der Strahlung* (On the quantum theory of radiation), [37.2]. In 1961 the possibility of obtaining stimulated emission in semiconductors was discussed by *Bernard* and *Duraffourg* who, for the first time, derived the condition for lasing action in semiconductor materials [37.3]. This became known as the Bernard–Duraffourg condition, as discussed later in this chapter. In the following year, the first reports of lasing action in semiconductor materials were published by four independent groups, *Nathan* and co-workers [37.4], *Hall* and co-workers [37.5], *Quist* and co-workers [37.6] and *Holonyak* and co-workers [37.1]. These lasers were based upon GaAs which, with its direct band gap, made it suitable for use as an optical source. The first devices consisted of simple p–n homo-junctions which have a single interface between the n- and p-doped regions. With a wavelength of near to 900 nm, these lasers emitted in the near-infrared region of the electromagnetic spectrum. Following on from his success with LEDs, *Holonyak* produced visible (red) semiconductor lasers. The first semiconductor lasers had very high threshold current densities, J_{th} (defined later in this chapter), and could only be operated under pulsed conditions. This made such devices impractical but started a period of intensive research into produc-

ing the first continuous-wave (CW) room-temperature semiconductor-based laser. After much investment into developing the growth technology of liquid-phase epitaxy (LPE), it became possible to produce a high-quality double heterostructure consisting of GaAs sandwiched between higher-band-gap $\text{Al}_x\text{Ga}_{1-x}\text{As}$ layers. The double heterostructure brought two key advantages over the homojunction; firstly, the lower-band-gap GaAs region formed a reservoir for the carriers (carrier confinement) where they could recombine across the band gap, and secondly, the higher refractive index of GaAs with respect to $\text{Al}_x\text{Ga}_{1-x}\text{As}$ provided better confinement of the optical field. These two improvements resulted in a significant reduction in J_{th} of two orders of magnitude and enabled CW operation at room temperature to be achieved for the first time [37.7, 8]. Almost 30 years later, in 2000, Alferov and Kroemer were co-recipients of the Nobel prize for physics for their pioneering work on the development of semiconductor heterostructures. In the late 1970s further improvements in semiconductor growth technology led to the development of molecular-beam epitaxy (MBE) and vapour-phase epitaxy (VPE) which enabled increasingly thin layers to be grown reproducibly. Layer thicknesses of the order of less than 100 \AA became achievable and introduced the regime in which quantum-confinement effects could be harnessed. These quantum well (QW) structures [37.9] brought about further improvements in laser performance, including a further increase in carrier confinement, narrower line width and extended wavelength tunability for a given material composition. The splitting of the degeneracy of the valence band also resulted in a reduced density of states at the top of the valence band. These improvements led to a substantially reduced J_{th} . In 1986, Adams, and also Yablonoitch and Kane, independently predicted that the introduction of biaxial strain into the active region of quantum wells would result in a further improvement in the laser characteristics [37.10, 11]. The proposed benefits of strain included a further reduction in the density of states at the top of the valence band (for compressive strain) and the ability to tailor the symmetry of the carrier distribution to that of the laser beam. The introduction of tensile strain made it possible to produce a semiconductor laser with transverse magnetic (TM) polarisation, something that was not previously possible. Strained-layer quantum wells are now included in the majority of commercially available semiconductor laser products. Recent material developments include quantum dot lasers, in which carriers are restricted in all three dimensions. There is a major

effort to develop quantum dot (QD) lasers with better performance than existing quantum well lasers. More than 20 years ago the first theoretical prediction [37.12] showed that using three-dimensionally (3D)-confined structures with an atomic-like discrete density of states in the active region of semiconductor laser should allow the development of devices with low threshold current density and very high thermal stability. Since this time, quantum dot lasers have been demonstrated with record low room-temperature threshold current densities, $< 20 \text{ A/cm}^2$ [37.13]. Work is ongoing to produce temperature-insensitive quantum dot lasers, particularly at $1.3 \text{ }\mu\text{m}$.

The late 1970s and early 1980s also gave rise to the development of single-mode lasers such as the distributed feedback (DFB) laser which have made long-haul optical communications possible [37.14]. The development of such advanced semiconductor laser devices spawned research into other semiconductor optoelectronic devices such as monolithic tunable lasers (discussed in detail by [37.15]), the semiconductor optical amplifier (SOA), optical modulators and advanced photodetectors. These devices are discussed in the latter part of this chapter.

In parallel with the developments mentioned above, other technologies were being investigated such as the vertical-cavity surface-emitting laser (VCSEL) originally proposed by Iga in 1977 and demonstrated by his group in 1979 (for a comprehensive review see [37.16]). VCSELs promise low-cost single-mode lasers which can easily be made into arrays. There remains intense activity to develop VCSELs for operation at the important telecommunications wavelength of $1.55 \text{ }\mu\text{m}$. VCSELs are discussed in later in this chapter. Other devices of note include the quantum cascade laser (QCL) developed by Capasso and co-workers in 1994 [37.17]. The development of QCLs was driven by the need to produce lasers emitting in the mid-infrared (mid-IR) ($\approx 3\text{--}12 \text{ }\mu\text{m}$) for gas sensing and environmental monitoring applications. For conventional interband lasers as discussed above, this requires narrow-band-gap materials which are much less developed than materials such as GaAs and InP. QCLs get around this problem by utilising *intra*-band transitions involving only one type of carrier, e.g. electrons (thus they are unipolar devices), and can be grown using conventional GaAs- or InP-based materials. In such devices, the carrier cascades through several quantum wells, giving rise to many photons per injected electron, quite unlike conventional interband devices. Clearly, QCLs offer great possibilities for the future development of mid-IR lasers

and perhaps, with suitable materials such as GaN, they may allow emission in the near-IR (for a review see [37.18]).

Unfortunately, it is impossible to go into detail about the developments of the full range of optoelectronic de-

vices in a single book chapter. However, we hope that this chapter provides a basic grounding on the relevant physics of the most important optoelectronic devices allowing the interested reader to investigate further, starting with the bibliography.

37.2 Light-Emitting Diodes and Semiconductor Lasers

37.2.1 Carrier–Photon Interactions in Semiconductors

In its simplest form, a semiconductor can be considered as a system containing two energy bands populated with electrons. In such a system there exist three possible processes by which the electrons can move between the two bands: the spontaneous emission, absorption and stimulated emission processes, as shown schematically in Fig. 37.1. Spontaneous emission occurs when an electron in the conduction band with energy E_2 recombines with a hole in the valence band at a lower energy E_1 . The difference in energy, $(E_2 - E_1)$ is emitted in the form of a photon. This process, as its name implies, is random and photons may be emitted in any direction with arbitrary polarisation. The probability of spontaneous emission is proportional to the density of electrons in the conduction band (n) and to the density of holes in the valence band (p). In the absorption process, an electron in the valence band is promoted to the conduction band by the absorption of a photon with an energy equal to the optical band gap. The probability of absorption is

proportional to the photon density, the density of electrons in the valence band and the density of empty states in the conduction band. The stimulated emission process occurs when a photon of energy $E_2 - E_1$ interacts with an electron in the conduction band, causing it to recombine with a hole in the valence band thereby generating a photon. The photon released by this process has both identical energy, phase and momentum to that of the incident photon. The probability of stimulated emission is therefore proportional to n , p and the photon density. In contrast to spontaneous emission, stimulated emission produces photons that are essentially identical and therefore very pure monochromatic light is generated.

At room temperature in an undoped semiconductor, there are far fewer electrons in the conduction band than in the valence band. As a consequence, absorption is far more likely than emission. To achieve optical gain, the probability of stimulated emission must exceed that of absorption. By applying either an electrical current (electrical pumping) or by injecting light with photon energies greater than the transition energy (optical pumping), it is possible to inject electrons into the conduction band and holes into the valence band. Electrical pumping is used for practical devices.

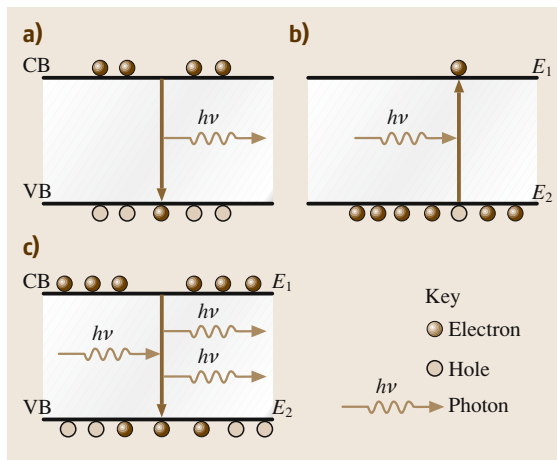

Fig. 37.1a–c The three electron–photon interactions in semiconductors: (a) spontaneous emission, (b) stimulated absorption, and (c) stimulated emission

37.2.2 Direct- and Indirect-Gap Semiconductors

Semiconductors may exist in two basic forms where the band gap is either direct or indirect. Whether or not the band gap is direct or indirect has a profound influence on their suitability for use in optoelectronic devices. Figure 37.2 illustrates the difference between a direct- (e.g. GaAs) and an indirect-band-gap (e.g. Ge) semiconductor. It can be seen that for the direct-gap material, the conduction-band (CB) energy minimum occurs at the same k -value as the valence-band (VB) maximum (direct). In contrast, for the indirect-gap material the CB minimum lies at a different k -value to the VB maximum. For any electron transition, the total energy and momentum must be conserved. The photon wavevector has a magnitude given by $2\pi/\lambda$, where λ

Fig. 37.2 Band structure of a direct-gap semiconductor (GaAs) and an indirect semiconductor (Ge)

is typically $\approx 1 \mu\text{m}$, whilst the magnitude of the electron wavevector ranges between $-\pi/a$ and π/a within the first Brillouin zone, where a is the crystal lattice spacing, typically $\approx 1 \text{ \AA}$. Clearly therefore, the photon wavevector is much smaller than the possible electron wavevectors and hence, if a photon interacts with an electron, the transition must occur with virtually no change in wavevector, hence only vertical transitions are allowed. It is clear that such transitions can occur in the direct-band-gap semiconductor. However, in the case of indirect semiconductors, such transitions are only possible via the interaction of a phonon. Since this becomes a three-particle interaction, the transition probability is significantly reduced. Stimulated emission is inhibited in indirect-band-gap semiconductors and it is for this reason that direct-band-gap semiconductors (such as GaAs, InP and related alloys) are primarily used to produce photoemissive devices such as LEDs and lasers. Indirect semiconductors, such as elemental germanium or silicon are therefore impractical for the production of such devices. However, these are very effective semiconductor materials for detection, as will be discussed later in this chapter.

37.2.3 Emission and Absorption Rates and the Einstein Relations

The populations of electrons and holes in the conduction and valence bands respectively are governed by both the densities of states and the Fermi–Dirac occupation

probabilities. In a semiconductor, electron–electron and hole–hole scattering rates are typically $\approx 100 \text{ fs}$ whilst electron–hole recombination times are $\approx 1 \text{ ns}$. We can therefore assume that the electrons and holes are in thermal equilibrium with themselves and can be described using a Fermi–Dirac distribution. It is useful to define two quasi-Fermi levels. These are referred to as F_c and F_v , corresponding to the energy at which the occupation probability equals $\frac{1}{2}$ for electrons in the CB and VB, respectively. In thermal equilibrium, $F_c = F_v$. The corresponding energy-dependent Fermi functions are

$$f_c(E) = \frac{1}{1 + \exp\left(\frac{E - F_c}{k_B T}\right)} \quad \text{and} \quad f_v(E) = \frac{1}{1 + \exp\left(\frac{E - F_v}{k_B T}\right)}, \quad (37.1)$$

where k_B is the Boltzmann constant and T is the absolute temperature.

By considering each of the processes illustrated in Fig. 37.1 one can obtain mathematical expressions relating each of the processes to the another. If we label states in the VB as “1” and states in the CB as “2”, the absorption rate, r_{12} , for photons of energy, $h\nu$ is given by

$$r_{12} = B_{12} \rho_v f_v (1 - f_c) \rho_c P(h\nu) \quad (37.2)$$

where ρ_c and ρ_v are the CB and VB densities of states, respectively. $P(h\nu)$ is the photon density at energy $h\nu$ and B_{12} is the Einstein coefficient for the absorption process. In a similar way, the stimulated emission rate, r_{21} , may be written as

$$r_{21} = B_{21} \rho_c f_c (1 - f_v) \rho_v P(h\nu) \quad (37.3)$$

where B_{21} is the Einstein coefficient for the stimulated emission process. For the spontaneous emission rate r_{21}^{spon}

$$r_{21}^{\text{spon}} = A_{21} \rho_c f_c (1 - f_v) \rho_v. \quad (37.4)$$

A_{21} is the Einstein coefficient for the spontaneous emission process. Note that, since spontaneous emission does not require a photon to initiate the process, r_{21}^{spon} does not depend on $P(h\nu)$. Under steady-state conditions, the total upward transition rate must equal the total downward transition rate, thus

$$r_{12} = r_{21} + r_{21}^{\text{spon}}. \quad (37.5)$$

Thus, by combining equations (37.2)–(37.4), we obtain

$$\begin{aligned} B_{12} \rho_v f_v (1 - f_c) \rho_c P(h\nu) \\ = B_{21} \rho_c f_c (1 - f_v) \rho_v P(h\nu) \\ + A_{21} \rho_c f_c (1 - f_v) \rho_v. \end{aligned} \quad (37.6)$$

In thermal equilibrium ($F_c = F_v$),

$$P(h\nu) = \frac{A_{21}}{B_{12} \exp\left(\frac{h\nu}{k_B T}\right) - B_{21}}. \quad (37.7)$$

The standard expression for black-body radiation is given by Planck's law as

$$P(h\nu) = \frac{8\pi^3 n^3 (h\nu)^2}{(hc)^3} \frac{1}{\exp\left(\frac{h\nu}{k_B T}\right) - 1}. \quad (37.8)$$

Here, n is the refractive index of the semiconductor. For simplicity, here we assume that the medium is nondispersive. From these two expressions of $P(h\nu)$ we obtain the result that

$$B_{12} = B_{21} = B \quad (37.9)$$

and

$$A_{21} = B \frac{8\pi^3}{(hc)^3} n^3 (h\nu)^2. \quad (37.10)$$

37.2.4 Population Inversion

The quantity of greatest importance to semiconductor laser operation is the *net* stimulated emission rate, which may simply be calculated as $r_{\text{stim}} = r_{21} - r_{12}$. Positive values of r_{stim} mean that an optical wave will grow in intensity as it travels through the semiconductor, whilst a negative r_{stim} implies that the optical wave would be reduced in intensity. From (37.2) and (37.3), r_{stim} can be written as

$$\begin{aligned} r_{\text{stim}} &= r_{21} - r_{12} \\ &= B_{21} \rho_c f_c (1 - f_v) \rho_v P(h\nu) \\ &\quad - B_{12} \rho_v f_v (1 - f_c) \rho_c P(h\nu) \end{aligned} \quad (37.11)$$

therefore

$$r_{\text{stim}} = r_{21} - r_{12} = B \rho_c \rho_v (f_c - f_v) P(h\nu). \quad (37.12)$$

The ratio of spontaneous emission to net stimulated emission is given by

$$\begin{aligned} \frac{r_{\text{spon}}}{r_{\text{stim}}} &= \frac{A_{21} \rho_c \rho_v f_c (1 - f_v)}{B \rho_c \rho_v f_c (f_c - f_v) P(h\nu)} \\ &= \frac{A_{21} f_c (1 - f_v)}{B P(h\nu) (f_c - f_v)}. \end{aligned} \quad (37.13)$$

Combining (37.13) with (37.10) leads to

$$\frac{r_{\text{spon}}}{r_{\text{stim}}} = \frac{8\pi^3 n^3 (h\nu)^2}{(hc)^3} \frac{f_c (1 - f_v)}{P(h\nu) (f_c - f_v)}. \quad (37.14)$$

Using the expressions for f_c and f_v (37.1), this can be simplified to

$$\frac{r_{\text{spon}}}{r_{\text{stim}}} = \frac{8\pi^3 n^3 (h\nu)^2}{(hc)^3} \frac{1}{P(h\nu) \left[1 - \exp\left(\frac{h\nu - (F_c - F_v)}{k_B T}\right) \right]} \quad (37.15)$$

and consequently

$$\begin{aligned} r_{\text{stim}} &= r_{\text{spon}} \frac{(hc)^3}{8\pi^3 n^3 (h\nu)^2} \\ &\quad \times \left[1 - \exp\left(\frac{h\nu - (F_c - F_v)}{k_B T}\right) \right]. \end{aligned} \quad (37.16)$$

From this expression we see that, when $F_c - F_v = h\nu$, $r_{\text{stim}} = 0$. Thus, when the quasi-Fermi-level splitting equals the photon energy, the absorption and stimulated emission rates cancel. At this injection level, the semiconductor is effectively transparent. This is known as the Bernard–Duraffourg condition. For photons of energy $h\nu > F_c - F_v$, there will be absorption. However, for photons of energy $h\nu < F_c - F_v$ there is gain. This defines the condition necessary to achieve population inversion in the semiconductor and lasing action can occur when $F_c - F_v > E_g$.

37.2.5 Gain in Semiconductors

If $\alpha(h\nu)$ is the rate of gain/loss per unit length and $P(h\nu)$ is the photon density, then the rate at which the photon density increases/decreases per unit length is simply $\alpha(h\nu)P(h\nu)$. The corresponding rate of increase of photon density per unit time is then

$$r_{\text{stim}} = P(h\nu) \alpha(h\nu) \frac{c}{n} \quad (37.17)$$

where c/n is the speed of light within a semiconductor of refractive index, n . By equating our two expressions for r_{stim} [(37.16) and (37.17)] we find that

$$\begin{aligned} \alpha(h\nu) &= r_{\text{spon}} \frac{h^3 c^2}{8\pi^3 n^2 (h\nu)^2} \\ &\quad \times \left[1 - \exp\left(\frac{h\nu - (F_c - F_v)}{k_B T}\right) \right]. \end{aligned} \quad (37.18)$$

Under conditions of low pumping or at high photon energies ($h\nu \gg F_c - F_v$), (37.18) can be approximated to

$$\begin{aligned} \alpha(h\nu) &= -r_{\text{spon}} \frac{h^3 c^2}{8\pi^3 n^2 (h\nu)^2} \\ &\quad \times \exp\left(\frac{h\nu - (F_c - F_v)}{k_B T}\right) \end{aligned} \quad (37.19)$$

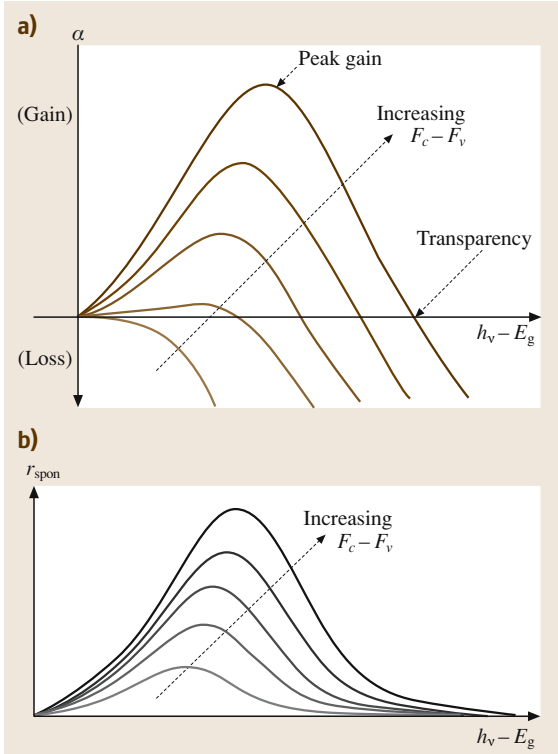

Fig. 37.3 (a) gain/loss and (b) spontaneous emission spectra as a function of increasing quasi-Fermi-level splitting

from which we have

$$r_{\text{spon}} = -\alpha(h\nu) \frac{8\pi^3 n^2 (h\nu)^2}{h^3 c^2} \times \exp\left(\frac{(F_c - F_v) - h\nu}{k_B T}\right) \quad (37.20)$$

Typical plots of the absorption and spontaneous emission rates can be seen in Fig. 37.3. From Fig. 37.3a it can be seen that, with increasing pumping level (increasing quasi-Fermi-level splitting), the semiconductor moves from purely absorption and becomes a gain medium. With increasing pumping, the spread of photon energies over which gain occurs also increases, with the peak gain moving towards higher photon energy. In Fig. 37.3b, the spontaneous emission rate is plotted as a function of photon energy. From this it can be seen that the emission spectrum is broad and corresponds to the output spectrum of a light-emitting diode (LED). With increasing pumping level, the integrated spontaneous emission increases whilst the peak shifts to higher photon energies. In practical devices, current-induced Joule heating

Fig. 37.4a-d Density of states in systems of differing dimensionality: (a) bulk, (b) quantum well, (c) quantum wire, and (d) quantum dot

may lead to a slight decrease in the band gap, which reduces the overall blue shift.

37.2.6 Density of States

As a semiconductor laser is put under forward bias, the quasi-Fermi levels in the conduction and valence bands move towards higher energies. The separation of the quasi-Fermi levels is dependent on the density of states $\rho(E)$ in the conduction and valence bands. At laser transparency, where the quasi-Fermi-level separation equals the photon energy, the transparency carrier density, n_{tr} and hence the threshold carrier density, n_{th} depend upon the number of states in a given energy range. By reducing the number of available states, n_{th} and consequently I_{th} (J_{th}), can be lowered. The density of states can be modified by changing the band structure. This can be achieved by reducing the dimensionality, thereby limiting the motion of the carriers, and also by introducing strain into the active region of the laser, as shall be described shortly.

Dimensionality

In conventional bulk semiconductor materials, the carriers have unrestricted motion in all directions and can be described by a 3D density of states,

$$\rho_{3\text{-D}} \propto m_{\text{eff}}^{3/2} \sqrt{E} \quad (37.21)$$

where m_{eff} is the effective mass. This is illustrated in Fig. 37.4a, where the shaded region indicates the carrier population as a function of energy. In such (bulk) devices there are relatively few states near to the band edges and hence the quasi-Fermi levels move towards

higher energies (where there is a larger concentration of available states) in order to achieve sufficient gain. This results in a broad output spectrum corresponding to radiative transitions over a wide energy range. By restricting the motion of the carriers along one dimension, as in quantum well structures, the density of states becomes independent of energy, with many states at the band edges. In a quantum well, the density of states is dependent only on the effective mass, m_{eff} and the quantum well width, L_z as:

$$\rho_{2\text{-D}} \propto \frac{m_{\text{eff}}}{L_z}. \quad (37.22)$$

In bulk structures, at the Brillouin zone centre of the valence band, the light- and heavy-hole bands are degenerate. Consequently, as the laser is pumped, states that do not contribute to the gain of the lasing mode also become filled. In a quantum well, the energy states form discrete levels. For an infinite square well, the confinement energy of the n^{th} energy level E_n is dependent on the quantum well width L_z and the growth-direction effective mass m_{eff}^z , and at the zone centre can be simply expressed analytically as

$$E_n = \frac{\hbar^2}{2m_{\text{eff}}^z} \left(\frac{n\pi}{L_z} \right)^2. \quad (37.23)$$

Thus, in a quantum well, the degenerate heavy- and light-hole bands become split (due to the difference in m_{eff}^z), resulting in a further reduction in the density of states at the valence-band Brillouin zone centre. Therefore in a quantum well laser, a higher proportion of the filled states can contribute to the gain of the lasing mode.

Further improvements in carrier confinement can be achieved by moving towards quantum wire or even quantum dot structures. In quantum wire lasers, the carriers are further confined, allowing freedom of movement along one direction only (Fig. 37.4c). In principle, such structures can be realised, e.g. by growth along lithographically defined V-grooves and lasers have been successfully produced in this manner [37.19] although the complexity of the processing has meant that they have yet to become a commercial product. In a quantum dot laser the carriers are confined still further so that they are restricted in all three dimensions (Fig. 37.4d). Thus, an ideal quantum dot is analogous to an atom. By completely restricting the carrier motion, one may theoretically expect to achieve temperature-insensitive operation [37.12]. Initial attempts to produce quantum dot lasers concentrated on lithographic processes but it was not until the successful demonstration of self-assembled growth (the

Stranski–Krastanov technique) that quantum dot lasers became a reality. Record low room-temperature threshold current densities ($< 20 \text{ A/cm}^2$) have been achieved using quantum dot lasers (e.g. [37.13]). However, due to the low gain, long lasers are required which increases the threshold current.

The influence of strain

A detailed discussion of strain in semiconductors is given in Chapt. 20 of this book. However, due to the enormous importance of strain in optoelectronic devices, in this section, we discuss the influence of strain on device characteristics. For many years, manufacturers of semiconductor lasers struggled to produce dislocation- and strain-free material. In 1986, it was suggested independently by *Adams* and by *Yablonovitch* and *Kane* that the incorporation of strain into the active layer of semiconductor lasers would lead to improved performance [37.10, 11]. Many of these benefits have since been demonstrated [37.20–22]. The majority of the lasers currently manufactured in the world today are based upon strained layers.

In a strained-layer structure, the lattice constant of the epilayer material a_{epi} is different from the lattice constant of the substrate a_{sub} on which it is grown. When a thin epilayer of this material is grown onto the much thicker substrate, the lattice constant of the grown epilayer becomes equal to that of the substrate, a_{sub} , and the epilayer is in a state of biaxial stress. The resulting net strain in the (x – y) plane of the layer ε is given by

$$\varepsilon_{\parallel} = \varepsilon_{xx} = \varepsilon_{yy} = (a_{\text{sub}} - a_{\text{epi}})/a_{\text{epi}}, \quad (37.24)$$

where it is assumed that the substrate is much thicker than the epilayer. Hence $a_{\text{epi}} > a_{\text{sub}}$ results in compressive strain while $a_{\text{epi}} < a_{\text{sub}}$ produces tensile strain.

Fig. 37.5 Illustration of unstrained, compressively strained, and tensile-strained layers. For the strained layers the epilayer expands (contracts) in the plane whilst expanding (contracting) in the growth direction, corresponding to compressive (tensile) strain respectively

Figure 37.5 shows the three possible types of epilayer growth: (a) compressively strained, (b) tensile strained and (c) unstrained. The sign convention used here is that positive strain indicates that the layer is under biaxial compression whilst a negative strain corresponds to a layer being in a state of biaxial tension. For compressive strain, when the lattice constant of the epilayer is reduced in the plane, the lattice constant in the growth direction, a_{\perp} , is increased. The strain in the growth direction ε_{\perp} ($= \varepsilon_{zz}$) is governed by Poisson's ratio σ and is given by

$$\varepsilon_{\perp} = \varepsilon_{zz} = -2\sigma\varepsilon_{\parallel}/(1 - \sigma). \quad (37.25)$$

In tetrahedral semiconductors, $\sigma \approx 1/3$ therefore, upon substituting this into (37.25), it can be seen that $\varepsilon_{\perp} \approx -\varepsilon_{\parallel}$. In order to understand how strain affects the band structure, it is useful to split the strain into an axial component ε_{ax}

$$\varepsilon_{ax} = \varepsilon_{\perp} - \varepsilon_{\parallel} \approx -2\varepsilon_{\parallel} \quad (37.26)$$

and a hydrostatic component, ε_{vol} ($= \Delta V/V$, the fractional change in volume of the epilayer)

$$\varepsilon_{vol} = \varepsilon_{xx} + \varepsilon_{yy} + \varepsilon_{zz} \approx \varepsilon_{\parallel}. \quad (37.27)$$

The axial and hydrostatic strain components affect the band structure as described in the next section. In direct-band-gap semiconductors, whilst strain has only a small effect on the conduction band, it greatly alters the valence-band structure.

The maximum layer thickness that can be grown under a state of strain is determined by the critical thickness h_c . Above this thickness, it becomes energetically favourable to relieve the strain energy through the formation of dislocations. Thus, in order to grow high-quality strained material it is necessary to keep the thickness of each layer below h_c . As the strain in a layer is increased, the corresponding critical thickness decreases. The maximum strain–thickness product for InGaAs/GaAs materials is $\approx 200 \text{ \AA\%}$ [37.23]. It is however possible to use alternating layers of compressive and tensile strain to produce zero-net-strain structures that can prevent the formation of dislocations. Strained-layer semiconductor lasers are often fabricated with strain-compensated wells and barriers when there are many strained quantum wells, thereby providing a large strain in the wells whilst reducing the overall strain in the structure.

The introduction of strain into the active region of semiconductor diode lasers brings about several changes in the band structure. The initial predictions of Adams and Yablonoitch and Kane concentrated on

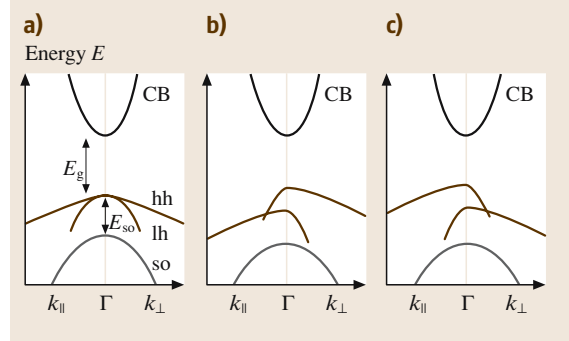

Fig. 37.6a–c Effects of strain for a bulk-like direct-band-gap semiconductor for (a) unstrained, (b) tensile strain, and (c) compressive strain

the benefits of compressive strain. It has since been shown that tensile strain can also enhance laser performance [37.24–26]. In the previous section, it was shown that the strain in an epilayer can be split into purely axial and hydrostatic components, ε_{ax} and ε_{vol} , respectively. The axial component of the strain splits the cubic symmetry of the semiconductor and hence the degeneracy of the heavy- and light-hole valence bands at the Brillouin zone centre is lifted (it should be noted that the valence band will already be nondegenerate in a quantum well due to the effects of quantum confinement). In addition, the valence-band dispersion becomes anisotropic. In the case of compressive strain the heavy-hole band is moved to higher energy with respect to the light-hole band, while the opposite is true for tensile strain. Also, for compressive strain the *in-plane* (x – y) mass becomes lighter than the mass in the growth (z) direction. Again, the opposite is true for tensile strain. The hydrostatic component of the strain causes an increase in the mean band gap for compressive strain and a decrease in the mean band gap for tensile strain. These effects on the band structure of a strained *bulk-like* material are shown schematically in Fig. 37.6.

Due to the much reduced in-plane highest hole band mass, the density of states in a compressively strained laser is lower than that for an unstrained device. As a result, n_{tr} is decreased, which not only lowers the amount of unwanted spontaneous emission [37.27] but also reduces carrier-density-dependent nonradiative processes such as Auger recombination [37.28]. Also, due to the increased heavy- and light-hole band splitting, carrier spill-over into higher sub-bands can be substantially reduced. Consequently, compressively strained lasers have been shown to have much lower threshold current densities than similar unstrained devices [37.20, 29].

Fig. 37.7a–c Schematic illustration of the valence-band alignment for (a) unstrained bulk-like, (b) compressive strain, and (c) tensile strain

To understand the improvement in performance of tensile-strained lasers it is necessary to examine the character of the valence band. The heavy-hole band consists of $1/2$ x -like states and $1/2$ y -like states but contains no states with z -like character. In contrast, the light-hole band consists of $1/6$ x -like states, $1/6$ y -like states and $2/3$ z -like states. y -like states contribute to transverse electric (TE) gain where the electric field oscillates across the facet (y -axis) and z -like states contribute to transverse magnetic (TM) gain, where the electric field oscillates along the growth direction. x -like states contribute only to spontaneous emission (SE), as the electric field vector lies in the propagation direction of the lasing mode. This is illustrated in Fig. 37.7. In bulk, unstrained quantum well and compressively strained quantum well lasers the lasing mode is always TE-polarised as $g_{\text{th}}(\text{TE}) < g_{\text{th}}(\text{TM})$. With the inclusion of tensile strain in the quantum wells of semiconductor lasers it became possible for the first time to produce a device with TM polarisation [37.25].

From Fig. 37.6 it can be seen that the in-plane mass of a tensile-strained laser is relatively large, resulting in

an increased density of states. However, from Fig. 37.7 it can be seen that the top of the valence band in a tensile-strained device contains $2/3$ z -like states, which can contribute to TM gain. Only $1/3$ of the injected carriers will *not* produce gain in the lasing mode, compared with $2/3$ in unstrained (bulk-like) and $1/2$ in compressively strained QW devices. Hence, tensile-strained lasers can also exhibit a lower threshold current [37.25]. However, if only a moderate amount of tensile strain is incorporated into the quantum well, the threshold current will increase due to the heavy- and light-hole sub-bands becoming degenerate.

37.2.7 Optical Feedback in a Fabry–Perot Laser Cavity

The probability of stimulated emission depends not only on maintaining population inversion, but also on the photon density. In a laser, the photon density is sustained by the use of optical feedback. In a gas laser, optical feedback is realised by the use of partially metallised mirrors, which form a Fabry–Perot cavity around the gain medium. When the light reaches the end of the cavity, a certain fraction (R) is reflected back into the gain medium, where it again becomes available to stimulate the emission of further photons. In a standard edge-emitting semiconductor laser, the same principle is used but the mirrors are formed by cleaving the semiconductor along a crystallographic plane, (most commonly the $[110]$ plane) forming laser facets. This is illustrated in Fig. 37.8. By using as-cleaved facets the resulting reflectivity, R is typically $\approx 30\%$ due to the refractive-index step between the laser material and (usually) air. This can be either increased or decreased with suitable facet

Fig. 37.8 Schematic diagram of a Fabry–Perot edge-emitting laser

Fig. 37.9 Illustration of gain in a semiconductor laser. The cavity mode that lies closest to the material gain peak at threshold will lase

coatings. Semiconductor lasers usually have roughened sides as a result of the fabrication process. This has the desirable effect of reducing the reflectivity of the sides of the laser and hence reduces the probability of generating unwanted transverse modes.

The application of optical feedback using a Fabry–Perot cavity has the effect of producing Fabry–Perot resonances or modes in the output spectrum of the laser. From Fig. 37.8 it can be seen that the optical field will form a standing wave when the cavity length is equal to an integer number of half wavelengths, given by

$$\frac{m\lambda}{2} = nL_{\text{cav}} \quad m = 1, 2, 3, \dots \quad (37.28)$$

where m is the (integer) number of half-wavelengths, λ is the lasing wavelength (as measured), n is the refractive index of the laser cavity and L_{cav} is the cavity length (typically $250 \mu\text{m} \leq L_{\text{cav}} \leq 1500 \mu\text{m}$). It can be seen that the maximum wavelength that the cavity can support is $\lambda = 2nL_{\text{cav}}$. If (37.21) is rearranged for λ and differentiated with respect to m , the mode spacing, $\Delta\lambda$ is found to be

$$\Delta\lambda = \frac{\lambda^2}{2nL_{\text{cav}}} \quad (37.29)$$

Thus, the possible modes of a semiconductor laser consist of a comb of many hundreds of delta functions spaced $\Delta\lambda$ apart, as illustrated in Fig. 37.9. For a typical $1.5\text{-}\mu\text{m}$ laser with $L_{\text{cav}} = 500 \mu\text{m}$ and $n \approx 3.2$, $\Delta\lambda \approx 0.7 \text{ nm}$. The wavelength at which lasing occurs is therefore determined by both the material gain curve and the mode spacing. The mode which lies closest to

the peak of the material gain curve at threshold will lase (Fig. 37.9) although other modes near to the gain peak may also be present in the output spectrum of an edge-emitting Fabry–Perot laser. With increasing bias however, the relative strengths of these modes will decrease with respect to the dominant lasing mode. This produces a very narrow and spectrally pure output, in stark contrast with the spontaneous emission spectrum of an LED.

37.2.8 Wave-Guiding

As discussed earlier in this chapter, the stimulated emission process is not only dependent on the carrier density, but also on the photon density within the laser cavity. In particular, it is a requirement that the photon density is maintained as high as possible so that the probability of stimulated emission is maximised whilst still allowing sufficient radiation to escape. As the optical field propagates along the laser cavity, it can extend in both the growth (z) and transverse (y) directions. Hence it is necessary for the optical field to be confined along two directions. In a semiconductor laser, wave-guiding can be accomplished by two methods: index-guiding and gain-guiding. Index-guiding is achieved by surrounding the active region with a material of larger band gap and hence, lower refractive index. In the *growth* direction of an edge-emitting double-heterostructure semiconductor laser the optical field is always index-guided. Figure 37.10 shows an example of index-guiding in a typical double-heterostructure laser together with the associated refractive-index profile in the growth direction. Index-guiding confines most of the optical field within the active region due to total internal reflection at the cladding heterojunctions with only a small fraction

Fig. 37.10 Wave-guiding in a double heterostructure

of the field evanescently decaying into the higher-band-gap layers. The degree of confinement depends upon the refractive-index step between the active region and the surrounding layers.

In the transverse direction, the optical field can be confined by either index- or gain-guiding mechanisms. Gain-guiding arises from a weak current-induced change in refractive index across the active region caused by the nonuniform carrier distribution. Index-guided structures can be considered as either strongly index-guided or weakly index-guided, corresponding to either a large or small refractive-index step in the transverse direction. Gain-guided structures are easier to fabricate than index-guided structures but are less effective in confining the optical field when compared with index-guided structures [37.30].

37.2.9 Carrier Confinement

In addition to confining the optical mode, laser characteristics can be greatly enhanced by improving the confinement of the electrons and holes, thereby increasing the probability of radiative recombination. The first laser structures [37.1, 4–6] were based upon sin-

gle p–n junctions (homojunctions). In such structures, the injected electrons and holes recombine close to the junction. However, due to the nonuniform carrier distribution, as the electrons diffuse out of the gain region, there is a variation in gain with position. In addition, due to the small difference in refractive index at the edge of the gain region, a large amount of the optical field spreads into absorbing regions. Thus, the combination of poor carrier and field confinement gives rise to large threshold current densities $\approx 10^5 \text{ A/cm}^2$ in homojunction lasers. The development of the double-heterostructure laser [37.7, 8] brought about a large decrease in J_{th} of two orders of magnitude. This results from the greatly improved carrier confinement due to the difference in the band gap between the active and cladding layers, which forms a potential barrier to the carriers. A further improvement in carrier confinement is obtained with quantum well structures. In a quantum well laser the injected carriers rapidly diffuse into the thin ($\approx 25\text{--}150 \text{ \AA}$) quantum well layers [37.9]. Due to the large potential barriers between the well and barrier material it is difficult for the carriers to subsequently escape. In addition to improved carrier confinement, quantum well lasers offer many other benefits over bulk lasers as discussed later in this chapter. Figure 37.11 illustrates the improvement in carrier confinement obtainable on going from homojunctions to double heterostructures and quantum well laser structures.

37.2.10 Current Confinement

The threshold current of semiconductor lasers can be further decreased by reducing the area of the device that is being electrically pumped. Reducing the threshold current can also suppress current-heating effects and extend the operating lifetime of the laser. Current confinement can also help to produce a stable fundamental mode. There are several fabrication techniques and associated laser structures designed to increase current confinement [37.30]. The ridge structure Fig. 37.12a is a weakly index-guided type of laser. In this structure, following the epitaxial growth of the complete layer structure, the wafer is etched to produce a ridge that is $\approx 2\text{--}10 \mu\text{m}$ wide. The wafer is then coated with a dielectric (usually SiO_2) and metallised. The weak index-guiding is provided by the large refractive-index step between the active region material and the dielectric. The current is directly injected into the ridge and therefore travels through a relatively narrow region of the device. The two main other structures are strongly index-guided buried-

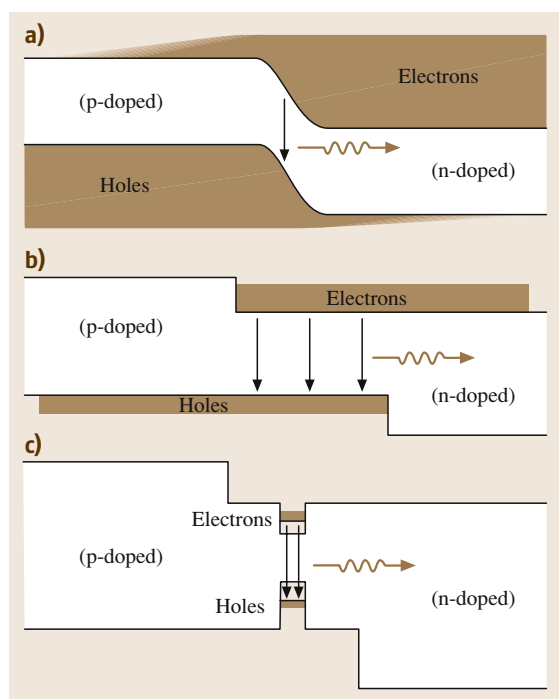

Fig. 37.11a–c Advances in carrier confinement (a) homojunction, (b) double heterostructure, and (c) quantum well

Fig. 37.12a–c Schematic diagrams of typical long-wavelength InP lasers **(a)** ridge structure, **(b)** double-channel planar buried heterostructure (DCPBH), and **(c)** semi-insulating planar buried heterostructure (SIPBH)

heterostructure (BH) devices. In double-channel planar buried heterostructure (DCPBH) lasers (Fig. 37.12b), following the growth of the layer structure, two channels, $\approx 3 \mu\text{m}$ deep and $\approx 10 \mu\text{m}$ wide, are chemically etched, forming a mesa. After cleaning, n- and p-doped current blocking layers are grown followed by the cladding and contacting layers. The current confinement is provided by the reverse-biased p–n junctions that surround the mesa.

The final structure considered is the semi-insulating planar buried heterostructure (SIPBH), as can be seen in Fig. 37.12c. In a similar way to the DCPBH devices, SIPBH lasers are based upon an etched mesa. In an SIPBH device the current confinement is provided by semi-insulating layers that surround the mesa. In these structures, after wet-chemically etching the wafer to form the mesa (typically $1\text{--}2 \mu\text{m}$ wide and $2\text{--}3 \mu\text{m}$ high) an Fe-doped layer is grown, followed by

an n-doped anti-diffusion layer, p-doped cladding and contacting layers. The resistivity of the Fe-doped regions surrounding the mesa is typically $\approx 10^8 \Omega \text{ cm}$ thereby ensuring that the current only flows through the active region. Buried heterostructure lasers tend to have lower threshold currents than ridge structures due to the combination of excellent current and optical field confinement. For high-speed applications such as telecommunications, SIPBH devices outperform DCPBH lasers due to their much lower parasitic capacitance.

37.2.11 Laser Threshold and Efficiency

In Sect. 37.2.4, the condition for material transparency was derived. In a laser structure the threshold is reached when the total gain is equal to the optical losses as the wave travels along the cavity plus the (useful) loss of light from the facets (mirror loss). If we consider the laser cavity shown in Fig. 37.8, the threshold gain condition, g_{th} is given by

$$g_{\text{th}} = \frac{1}{\Gamma} [\alpha_m + \alpha_i] \\ = \frac{1}{\Gamma} \left[\frac{1}{2L_{\text{cav}}} \ln \left(\frac{1}{R_1 R_2} \right) + \alpha_i \right], \quad (37.30)$$

where R_1 and R_2 are the facet reflectivities, α_m is the mirror loss and α_i is the internal loss per unit length in the *entire* structure including scattering losses, free-carrier absorption, and inter-valence-band absorption [37.31]. Γ is the optical confinement factor, which is equal to the fraction of the optical field intensity that overlaps the active region. This therefore accounts for the fact that not all of the optical field will give rise to gain. Note that g_{th} is the threshold gain per unit length of the device. For a typical $1000\text{-}\mu\text{m}$ -long $1.5\text{-}\mu\text{m}$ quantum well device ($\Gamma \approx 0.02$) with as-cleaved facets ($R_1 = R_2 \approx 0.3$) and $\alpha_i = 10 \text{ cm}^{-1}$, $g_{\text{th}} \approx 1100 \text{ cm}^{-1}$.

Fig. 37.13 Variation of the light output (solid curve) and carrier density (dashed curve) as a function of the injection current. Above threshold, the light output increases abruptly whilst the carrier density becomes pinned

The carrier density required to reach g_{th} is termed n_{th} , and the corresponding current (density) is termed I_{th} (J_{th}). Figure 37.13 shows how the light output and carrier density increase as current is injected into the laser structure. Below threshold, increasing the current causes the Fermi-level splitting to increase, thereby increasing the electron and hole (carrier) densities in the active region of the laser. In this regime, the laser is acting as an LED and spontaneous emission is produced. However, the electrical-to-optical conversion efficiency is relatively low ($\approx 1\%$). In practice nonradiative recombination processes (as discussed in the next section) cause the carrier density to have a nonlinear dependence on current below the laser threshold. At threshold, the stimulated lifetime decreases, causing each additional injected carrier to undergo stimulated emission. These carriers rapidly transfer to the valence band with the production of a photon via stimulated emission giving rise to an abrupt increase in the light output. Thus, at threshold the carrier density becomes pinned at n_{th} since every additional carrier quickly undergoes stimulated emission. Hence, above threshold the intrinsic *differential* quantum efficiency, η_d , of the lasing process can be as high as 100% in an ideal laser. However, effects including carrier leakage, absorption and self-heating can reduce the overall measured differential quantum efficiency.

The differential quantum efficiency, η_d , is defined as the ratio of the incremental number of photons emitted from the facets to the incremental number of carriers injected into the laser (above threshold), thus

$$\eta_d = \frac{dL}{dI} \frac{e}{h\nu}, \quad (37.31)$$

where L is the optical power emitted from both facets, e is the electronic charge and $h\nu$ is the photon energy (the lasing energy). Thus, η_d can simply be determined from the light-current characteristic (providing that all of the stimulated light is collected), η_d can more generally be defined from

$$\eta_d = \eta_i \left(\frac{\alpha_m}{\alpha_i + \alpha_m} \right); \quad (37.32)$$

η_i is the *internal* quantum efficiency and accounts for the fact that, in a real laser, not all of the injected carriers will result in the production of a photon. This may be due to inefficient injection of carriers into the active region of the laser (dependent on both the laser materials and the geometry of the laser). It is convenient

to rewrite (37.32) in terms of the inverse efficiency so that

$$\begin{aligned} \frac{1}{\eta_d} &= \frac{1}{\eta_i} \left(\frac{\alpha_i + \alpha_m}{\alpha_m} \right) = \frac{1}{\eta_i} \left(\frac{\alpha_i}{\alpha_m} + 1 \right) \\ &= \frac{1}{\eta_i} \left[\frac{2\alpha_i L_{cav}}{\ln \left(\frac{1}{R_1 R_2} \right)} + 1 \right]. \end{aligned} \quad (37.33)$$

If R_1 and R_2 are known (easily calculated), by measuring η_d for lasers with several different cavity length taken from the same wafer and plotting a graph of $1/\eta_d$ versus L_{cav} one can obtain a value for both η_i (from the intercept) and α_i (from the slope/intercept).

From Fig. 37.13 it is clear that the *overall* efficiency of the laser will depend on both the differential quantum efficiency η_d , which we wish to maximise, *and* the threshold current I_{th} , which we would like to minimise. In the discussion thus far, the threshold current has been described only in terms of a spontaneous emission current. In practice there exist many other recombination paths that contribute to the laser threshold. These are discussed in the next section.

37.2.12 Carrier Recombination Processes

When carriers are injected into a semiconductor laser there are many possible recombination paths. In an ideal semiconductor laser, above threshold, the carrier density pins, as illustrated in Fig. 37.13. Therefore, above threshold, any recombination path which depends upon n will also become pinned. However, the threshold current itself is determined by the different mechanisms by which carriers recombine in a real laser structure. In this section, the important radiative and nonradiative recombination mechanisms are briefly discussed. The threshold current of a semiconductor laser is defined as the current required to provide enough gain to reach the threshold gain level g_{th} . Due to differences between laser structures, it is frequently more useful to compare the threshold current density J_{th} between devices, which accounts for the overall area of the device that is being pumped, thereby allowing a useful comparison to be made between different device structures. In this chapter, the two are used interchangeably when discussing laser characteristics.

At threshold, the total current I can be expressed as the sum of the current paths as

$$I = eV(An + Bn^2 + Cn^3) + I_{leak} \quad (37.34)$$

Fig. 37.14 Spontaneous emission in a bulk semiconductor

where e is the electron charge, V is the active region volume and n is the carrier density (where we assume that the electron (n) and hole (p) densities are equal, $n = p$).

The An term is due to recombination at defects and is considered to be negligible in high-quality material. It does however make significant contributions to some laser materials, most notably InGaAsN/GaAs where it can account for up to 50% of I_{th} even in the best 1.3- μm devices [37.32].

The Bn^2 term corresponds to the radiative recombination of electrons and holes giving rise to spontaneous emission, as observed from LEDs, and semiconductor lasers operated below threshold. Radiative recombination occurs (for interband processes) when an electron in the conduction band recombines with a hole in the valence band, resulting in the spontaneous emission of a photon as illustrated in Fig. 37.14. For lasing to occur it is necessary to have spontaneous recombination to initiate the stimulated emission process. However, because spontaneous emission is a random process, emitting photons in all directions over a broad energy range, only a small fraction of the photons can couple to the laser gain. Hence for efficient laser operation it is desirable that the amount of unwanted spontaneous emission is reduced.

The Cn^3 term describes *nonradiative* Auger recombination. In an Auger recombination process, the energy of a recombining electron-hole pair that would normally produce a photon, is instead given to a third carrier (electron or hole) which is excited further into its respective band. Thus, in an Auger recombination process, three carriers are involved, the initial electron-hole pair plus an additional electron or hole.

Fig. 37.15a,b The two primary Auger recombination processes: (a) CHCC producing hot electrons and (b) CHSH producing hot holes

The two main Auger recombination processes are illustrated in Fig. 37.15, where the closed circles represent electrons and open circles represent holes. In the conduction-hole-conduction-conduction (CHCC) process, the energy and momentum of a recombining conduction-band electron and valence-band hole are transferred directly to a second conduction-band electron, which is then excited into a higher-energy conduction-band state. In the direct conduction-hole-spin-hole (CHSH) process, the energy and momentum are transferred to a second valence-band hole, which is then excited into the spin split-off band. In addition to these direct Auger recombination processes, there may be phonon-assisted processes whereby the conservation

Fig. 37.16 Variation of the threshold current with lasing energy over the wavelength range 1.2–1.6 μm . With increasing wavelength (decreasing energy), the threshold current increases swiftly due to the increased probability of Auger recombination, as illustrated in the insets

Fig. 37.17 Threshold current (circles) and radiative current (squares) versus temperature for a 1.3- μm InGaAsP laser. The threshold current increases more strongly with temperature than the radiative current due to the thermally induced onset of Auger recombination

of momentum and energy of the carriers is relaxed by the emission or absorption of a phonon. These are however of less importance in 1.3- μm and 1.5- μm lasers [37.33]. It should be noted that Auger-generated carriers are very energetic and initially lie many $k_B T$ more than E_g above their respective band edges. Whilst these carriers quickly scatter back to thermal equilibrium, there is a finite probability that they will scatter from the active region into the cladding layers, thus forming an additional Auger-generated leakage current.

Auger recombination processes are very sensitive to the band gap, E_g , and are severely detrimental to laser performance. For emission wavelengths below 1 μm , the probability of an Auger recombination process occurring is small due to the near-vertical transitions that are required on an energy-momentum diagram, which decreases the probability of the process occurring (inset Fig. 37.16). However, as E_g decreases, the transitions become less vertical and the probability of finding a state for the *hot* Auger carrier increases. Auger recombination therefore begins to influence the performance of semiconductor lasers and by 1.5 μm it dominates their behaviour at room temperature, forming $\approx 80\%$ of the threshold current [37.28]. This is illustrated in Fig. 37.16 where the normalised variation of the measured threshold current with lasing energy was determined by performing high-pressure measurements on several lasers over the nominal wavelength

range 1.3–1.6 μm . With increasing lasing energy (band gap), the threshold current decreases strongly due to the lowered contribution of Auger recombination. Thus, long-wavelength lasers are more susceptible to Auger recombination. Auger recombination is also largely responsible for the high-temperature sensitivity of the threshold current of 1.3- μm and 1.5- μm semiconductor lasers. In Fig. 37.17 we plot the temperature dependence of the threshold current (circles) for a 1.3- μm InGaAsP laser. The squares correspond to the measured radiative current as determined from spontaneous emission measurements [37.28]. At low temperature, the threshold current follows the radiative current very closely, however, above ≈ 160 K, the threshold current increases strongly due to thermally activated Auger recombination. This is primarily due to the n^3 dependence of the Auger current but also because the Auger coefficient C is thermally activated [37.34].

I_{leak} is associated with heterobarrier leakage and current spreading around the active region. With increasing temperature there is an increasing probability that electrons in the conduction band and holes in the valence band will have enough thermal energy to escape from the quantum wells. This is termed heterobarrier leakage. Here these carriers may recombine radiatively (at shorter wavelengths) or nonradiatively. If they have sufficient energy, they may even escape into the cladding layers. The probability of carriers escaping into the cladding layers depends upon the position of the quasi-Fermi levels with respect to the cladding band edge, as illustrated in Fig. 37.18. With increasing temperature, the thermal spread of carriers broadens and the population of unconfined carriers at threshold increases, thereby increasing the threshold current. For diffusion-driven leakage of electrons, the leakage current I_{leak} can be described via an activation energy E_a , equal to the difference in en-

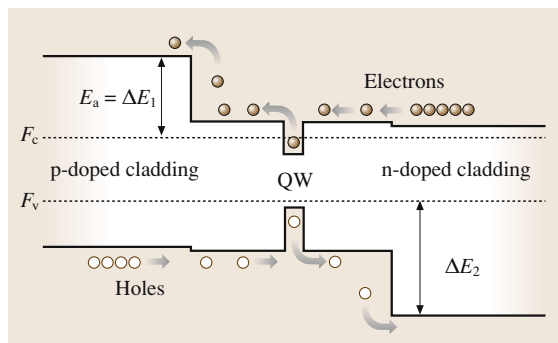

Fig. 37.18 Carrier leakage in a quantum well (QW) semiconductor laser

ergy between F_c and the lowest (Γ , L or X) CB edge of the cladding layer. Thus

$$I_{\text{leak}} = I_0 \exp\left(-\frac{E_a}{k_B T}\right), \quad (37.35)$$

where k_B is the Boltzmann constant, T is the temperature and I_0 is independent of temperature. As with Auger recombination, carrier leakage is strongly temperature-dependent and can lead to a large change in the threshold current with temperature. For this reason, much effort has been put into designing lasers which minimise carrier leakage. In III–V semiconductors, due to the large hole effective mass, F_v moves towards the valence band at a much slower rate than F_c moves towards the conduction-band edge. For InGaAs(P)-based materials as used in 1.3- μm and 1.5- μm lasers, the quantum well to barrier/SCH band offset in the conduction band is much lower than the valence-band offset. Additionally, holes have a much lower mobility than electrons. Consequently, the overflow of electrons is generally considered to be more significant compared to the overflow of holes in this materials systems. Carrier leakage is a particular problem for visible semiconductor lasers for which the Al-containing layers may be close to, or indeed are, indirect, whereby the conduction-band X-minima are at a lower energy than the conduction band Γ -minimum. Thus, electrons may thermally escape from the Separate confinement Heterostructure (SCH) into the cladding, forming a leakage current. An example of this is shown in Fig. 37.19 where the threshold current is plotted as a function of temperature for a 670-nm Al(GaInP) laser.

Fig. 37.19 Threshold current versus temperature for a 670-nm GaInP quantum well (QW) laser. The strong temperature sensitivity above 250 K is due to electron leakage into the X-minima of the AlGaInP barrier layers

The strong increase in threshold current with temperature is due to the thermal leakage of electrons from the GaInP QW via the SCH region into the X-minima of the AlGaInP barrier layers. At room temperature, leakage accounts for $\approx 20\%$ I_{th} at room temperature, rising to $\approx 70\%$ at 80°C at this wavelength [37.35]. Due to the smaller activation energy, shorter-wavelength devices suffer still further from carrier leakage and this, in practice, sets the lower wavelength limit for lasers produced using this material system.

37.2.13 Temperature Sensitivity and T_0

As described in the previous section, the threshold current of lasers operating in the visible and in the 1.3- μm to 1.5- μm range is very sensitive to the ambient temperature. From a commercial perspective, this is very unsatisfactory as these lasers are required to provide a constant light output for a given drive current above threshold all year round. However, throughout the year, the ambient temperature can typically vary significantly. Hence, further cost results from having to use expensive temperature-control electronics to stabilise the temperature and hence light output of these lasers. This can be seen in Fig. 37.20 where the power–current curves are plotted for a 1.3- μm laser over the temperature range 20 – 70°C . Clearly, by operating the laser at a constant bias current, the light output decreases considerably as the temperature decreases. In extreme cases the current may no longer be sufficient to reach laser threshold, at which point the device will no longer lase and the output would only be spontaneous emission (as in Fig. 37.20,

Fig. 37.20 Typical curves of power versus current for a 1.3- μm laser as a function of temperature. The large increase in threshold current with increasing temperature gives rise to a strong loss of power for a fixed bias current

for the 70 °C curve). In practical situations this therefore necessitates the use of temperature-control feedback electronics. These add considerable cost (many times the cost of the laser itself) to the system. This has become known as the T_0 problem. Around room temperature and over a limited range of temperature, the threshold current of many semiconductor lasers was observed to increase approximately exponentially with temperature [37.36]. Hence it is usual to write that $I_{th} = I_0 \exp(T/T_0)$, where I_0 is a constant and T_0 is the characteristic temperature of the threshold current given by

$$\frac{1}{T_0} = \frac{1}{I_{th}} \frac{dI_{th}}{dT} = \frac{d \ln(I_{th})}{dT}, \quad (37.36)$$

T_0 is usually expressed in units of Kelvin. It follows that a low value of T_0 corresponds to a high temperature sensitivity and vice versa. Hence, a high T_0 is desirable. Experimentally, T_0 can be determined from measurements of I_{th} from

$$T_0 = \frac{T_2 - T_1}{\ln \left[\frac{I_{th}(T_2)}{I_{th}(T_1)} \right]}, \quad (37.37)$$

where $I_{th}(T_1)$ and $I_{th}(T_2)$ are the threshold currents at T_1 and T_2 respectively and $T_2 > T_1$. In practice, over a wider temperature range, T_0 is *itself* temperature-dependent due to the temperature dependence of the recombination mechanisms that occur in the lasers. However, T_0 is a parameter often used to investigate the temperature dependence of the threshold current. For a typical 1.3- μm or 1.5- μm QW laser, $T_0 \approx 50$ –60 K. This is due to Auger recombination, as discussed above. It can be shown that, for an ideal QW laser, the maximum $T_0 = 300$ K around room temperature, where the threshold current is entirely due to radiative recombination [37.37]. Furthermore, by going to quantum dot lasers, due to the 3D-confinement effect, an infinite T_0 has been predicted [37.12]. Recently reported experimental work has shown that this may be possible by using p-doped quantum dot layers, which exhibit temperature-insensitive operation around room temperature [37.38].

37.3 Single-Mode Lasers

37.3.1 DFB lasers

In an ideal laser, the output spectrum would be very narrow with no side modes. In practice, the output spectrum of Fabry–Perot devices such as those described earlier in this chapter consists of several competing modes. This is due to the comb of Fabry–Perot modes, which overlap with the laser gain spectrum (shown earlier in Fig. 37.9). There are a number of laser devices which can be operated with high spectral purity. Perhaps the most important of these is the distributed feedback (DFB) laser. In a Fabry–Perot laser, the end facets provide optical feedback to give rise to provide sufficient gain to achieve threshold. Because the reflectivity of the end facets is only slightly wavelength-dependent (for

a given polarisation), this gives rise to several longitudinal modes. These are clearly visible in the output amplified spontaneous-emission spectrum of a Fabry–Perot laser, indeed this is one way in which the gain can be measured [37.39]. In contrast, in a DFB laser, there is an additional layer called the guiding layer (Fig. 37.21) grown close to the active layer. The guiding layer is essentially a grating consisting of a corrugated layer of a dissimilar-refractive-index semiconductor defined using lithographic and etching techniques. The guiding layer is usually overgrown although surface gratings are also possible and simpler to produce. The corrugations in the material provide a periodic variation in the refractive index along the laser cavity and hence the optical feedback is *distributed* along the length of the cavity. The forward and backward propagating waves will only interfere constructively if their frequency is related to the pitch of the grating. It can be shown that the correspondingly allowed modes lie symmetrically either side of the Bragg frequency of the grating. In practice, due to nonuniformity as a result of processing, or by artificially introducing a quarter-wavelength shift in the Bragg reflector, one of the modes may lase preferentially. DFB lasers are the mainstay of optical communications systems due to their single-mode behaviour with

Fig. 37.21 Simplified diagram of a distributed feedback (DFB) laser

high side-mode suppression and narrow line widths (≈ 0.1 nm). In an optical-fibre communication system, this allows for the simultaneous transmission of several data channels with closely spaced wavelengths around the fibre attenuation minimum of $1.55\ \mu\text{m}$. this is known as dense wavelength-division multiplexing (DWDM).

An added benefit of the grating in a DFB laser is that it may be used to artificially reduce the temperature sensitivity of the laser threshold current and lasing wavelength. Unlike Fabry–Perot lasers, which primarily emit at the mode closest to the gain peak, as discussed above DFB lasers can be made to emit at one fixed mode. The peak of the gain spectrum moves approximately at the same rate as that of the band gap ($\approx 0.5\ \text{nm/K}$) whilst the temperature dependence of the DFB mode follows the thermally induced change in the refractive index ($\approx 0.1\ \text{nm/K}$) which is much less temperature sensitive. Thus, DFB lasers are far less susceptible to thermally-induced mode hops. Furthermore, by carefully designing the peak of the gain spectrum to lie at a shorter wavelength than the DFB wavelength, one can effectively *tune* the DFB laser with increasing temperature resulting in, over a limited temperature range, a relatively temperature-independent threshold current. This has been demonstrated as a means of achieving cooler-less $1.3\text{-}\mu\text{m}$ lasers, albeit at the expensive of higher threshold currents.

37.3.2 VCSELs

Vertical-cavity surface-emitting lasers (VCSELs) differ from conventional semiconductor lasers due to the fact that the optical cavity lies in the growth direction, in the same direction as the current flow. The output of the laser is therefore emitted from the surface. There are several major advantages of VCSELs compared with edge-emitting lasers, which have led to a considerable amount of research being undertaken to produce VCSELs at a variety of wavelengths. Unlike edge-emitting lasers, once the semiconductor wafer has been metallised, it is very easy to test the devices prior to dicing them into individual chips. This represents a considerable cost saving. Forming laser arrays is obviously therefore much more straightforward with VCSELs and has led to the development of parallel data links based upon VCSELs and high-power VCSEL arrays. The small size of VCSELs (aperture diameter $< 10\ \mu\text{m}$) also gives rise to both single-mode behaviour and low threshold currents. Furthermore, due to the fact that the light is (usually) emitted from a circular geometry contact, the beam profile is circular, making fibre coupling much

Fig. 37.22 Schematic diagram of a vertical-cavity surface-emitting laser (VCSEL)

simpler. In contrast, edge-emitting lasers have an elliptical beam profile due to diffraction of the laser light from the end facet, requiring expensive corrective optics and active alignment with optical fibres.

Because the VCSEL emits from its surface, the optical cavity over which the optical field may experience gain is very short. Consequently, in order to reach the threshold gain level, the optical field needs to make several passes through the active region. This requires highly reflective end mirrors. At a typical III–V semiconductor–air interface, the refractive-index contrast gives rise to a reflectivity of $\approx 30\%$. This is enough to achieve sufficient gain to reach threshold in an edge-emitting laser, which is typically many hundreds of microns long. However, in a VCSEL, the cavity length is typically $\approx 0.1\ \mu\text{m}$, requiring mirror reflectivities $> 99\%$. This is achieved by sandwiching the active region between two multilayer dielectric mirrors (Fig. 37.22). These so called distributed Bragg reflectors (DBRs) consist of alternating high- and low-refractive-index quarter-wave-thick pairs. In a similar way to the DFB lasers discussed above, the DBR mirrors in VCSELs provide a high degree of wavelength-selective reflectance, providing that the sum of the optical thicknesses of each layer pair is equal to a half wavelength (i.e. $n_1d_1 + n_2d_2 = \lambda/2$, where n_i and d_i are the refractive index and thickness of each layer respectively), thereby giving rise to constructive interference at the desired wavelength. Typically, there may be 30 or so layers in each DBR to achieve sufficiently high reflectivity. It is useful to note here that a related device, the

resonant-cavity LED (RCLED), is similar to the VCSEL but contains far fewer DBR pairs in order that it does not lase, but instead produces narrow-band high-efficiency spontaneous emission. Whilst a large number of layer pairs in the VCSEL gives rise to a high reflectivity it may also decrease the quantum efficiency of the device and increase the operating voltage due to the large number of interfaces. Furthermore, due to free-carrier absorption and carrier leakage in the DBRs themselves, a high number of DBRs can degrade device performance [37.40]. The exact number of DBRs used is therefore a compromise which depends upon the operating wavelength of the VCSEL and the semiconductor material system on which it is based.

High-quality VCSELs have already been produced for emission at 650 nm and 850 nm (for plastic and silica fibre communications), for oxygen sensing using 760 nm VCSELs and high-power devices for emission at 980 nm [37.41]. However, there has been considerable difficulty in producing VCSELs at the telecommunications wavelengths of 1.3 μm and 1.55 μm . This is primarily due to the fact that GaAs/AlGaAs is the preferred system for making highly reflective DBRs due to the high refractive-index contrast between GaAs and AlAs. Such DBRs are therefore compatible with the GaAs substrates as used in devices below $\approx 1 \mu\text{m}$. However, for longer-wavelength devices, which are primarily based on InP substrates it is difficult to form highly reflective DBRs using InGaAsP/InP due to their low refractive-index contrast. Alternative methods of producing long-wavelength VCSELs are inherently process-intensive, using techniques such as wafer fusion in which the active layer and InGaAsP/InP DBR is first grown on an InP substrate whilst a GaAs/AlAs DBR is grown separately on a GaAs substrate. The active layer is then fused onto the GaAs/AlAs DBR and the InP substrate is then removed (see for example, [37.42]). The wafer fusion process is understandably both costly and difficult, and therefore methods of growing monolithic 1.3- μm and 1.55- μm VCSEL structures

using only a single GaAs substrate are particularly attractive. This has stimulated a great deal of research into producing GaAs-based active regions emitting at these wavelengths. In recent years there has been some success in achieving this by two approaches. The first approach is to use InAs/GaAs quantum dots as the active region. Quantum dot lasers with very low threshold current density ($< 20 \text{ A/cm}^2$) emitting at 1.3 μm have already been realised [37.13]. However, there are few reports in the literature on quantum-dot-based VCSELs. This is largely due to the difficulty in achieving sufficient gain from the quantum dots and can result in the need for several layers of quantum dots. In spite of this, quantum dots are showing promise for use in temperature-insensitive edge-emitting lasers and high-power lasers.

The second approach has been in the use of the so called dilute nitrides. In 1997, *Kondow* and co-workers originally proposed the use of InGaAsN/GaAs as an active material to achieve long-wavelength emission on GaAs [37.43]. This is due to the unusual band-gap bowing that occurs when small concentrations ($\approx 2\text{--}5\%$) of nitrogen are added to GaAs. By growing the alloy InGaAsN, one may achieve long-wavelength emission whilst maintaining a low or zero strain. Although material quality remains an issue, there have been several successful demonstrations of edge-emitting lasers and VCSELs based upon this material emitting at 1.3 μm [37.44–46]. The push towards 1.55- μm emission has been largely hampered by material quality issues although at the time of writing this chapter, there have been the first reports of low-threshold 1.5- μm edge-emitting lasers based upon InGaAsN/GaAs [37.47]. Other researchers have produced close-to-1.5- μm edge-emitting and VCSEL devices with the pentenary material InGaAsNSb/GaAs [37.48]. It is speculated that antimony may act as a surfactant to improve the quality of growth. The dilute nitride approach does at present appear to offer the best possibility of obtaining VCSELs emitting at the technologically important wavelength of 1.55 μm .

37.4 Optical Amplifiers

37.4.1 An Introduction to Optical Amplification

As a light pulse propagates through an optical communication system, the pulse becomes attenuated until eventually it is necessary to regenerate the pulse to keep

the signal above the background noise level. This was initially achieved by detecting the pulse using a photodetector, and then using the detected electronic pulse to trigger a laser giving a fresh output pulse. An alternative technique is to use direct optical amplification. This has been achieved for instance by doping optical fi-

bres with rare-earth elements such as erbium, forming an erbium-doped fibre amplifier (EDFA). Population inversion is achieved by exciting the erbium atoms at 980 nm or 1.48 μm , where the excited carriers decay to a level from which they can recombine to give stimulated emission at 1.55 μm , amplifying weak signals in the fibre. Amplification can also be achieved within conventional silica fibres using the Raman effect; by pumping the fibre with a high-power pump laser (total power $\approx 1\text{ W}$) at a fixed frequency above the signal frequency, Raman scattering gives rise to gain at a lower frequency (the difference is the phonon energy). Thus, by pumping an optical fibre at 1.45 μm one may achieve gain at 1.55 μm . The main advantage of Raman amplification compared with EDFAs is the fact that the gain curve may be dynamically tuned by judiciously using different wavelength pump lasers. The disadvantages of Raman amplification is that the overall gain is generally lower than an EDFA and cross-amplification effects can be a problem. For some applications, semiconductor optical amplifiers (SOAs) may be preferred.

37.4.2 Semiconductor Optical Amplifiers (SOAs)

The structure of a SOA is very similar to that of a laser, but with one significant difference: the reflectivity of the end facets, $R \approx 0$. This is achieved through the use of multilayer antireflection coatings together with angled facets or cavities. This suppresses lasing within the cavity, and eliminates reflected signals in the optical system.

The signal emerging from an optical fibre is, in general, randomly polarised and therefore it is very desirable that any optical amplifier provides gain that is independent of the direction of polarisation of the light. In a bulk heterostructure device, the TE and TM material gain are equal. However, the optical confinement factor Γ for

TE light polarised in the plane of the heterostructure is slightly larger than for TM light polarised perpendicular to the heterostructure plane, leading to a larger overall TE gain. As discussed earlier in this chapter, in a normal quantum well system the quantum confinement brings the heavy-hole band to the top of the valence band and light polarised in the TE mode is amplified considerably more strongly than light polarised in the TM mode. This problem can be overcome using strained-layer techniques. It is possible to grow the wells or the barriers with a small amount of tensile strain. This raises the light-hole band and the strain can be adjusted to increase the device TM gain until it is just equal to that of the TE gain. Work to date indicates that the relative gains in the two modes are sensitive to the magnitude of the amplifier current and so the gains are equal over a limited range.

Strained SOAs

Another more promising approach is to introduce both compressive- and tensile-strained wells alternately into the active region. The compressive wells provide gain predominantly to the TE mode and the tensile wells predominantly to the TM mode. The structure can then be designed to make the two gain modes equal. The initial work by Tiemeijer et al. from Philips concentrated on 1.3- μm devices [37.49]. They found that a combination of four compressive wells and three tensile wells each with 1% strain gave TE and TM gain within 1 dB of each other over a wide wavelength band and over an order of magnitude change in amplifier current. This structure is an excellent example of the flexibility in device design that is afforded by the introduction of strained-layer techniques. Other applications of such a structure include two-polarisation or two-frequency lasers, polarisation control elements and nonabsorbing strain-overcompensated mirrors in high-power lasers.

37.5 Modulators

37.5.1 Modulator Theory

Although it is possible to modulate the output from a semiconductor laser by directly modulating the injected current, in some applications requiring high-speed or low-power switching, it is advantageous to run the laser source CW and modulate the light subsequently [37.50]. This is basically because, unlike lasers,

semiconductor modulators are diodes operated in reverse bias. They therefore draw little current and, because there is no carrier injection, there is much less chirp.

Electroabsorption modulators make use of the fact that the presence of a large electric field adds a perturbation to the Schrödinger equation, which leads to a decrease in the band-gap energy E_g . Thus photons with

Fig. 37.23 Measured photocurrent spectra at 2 K of an InGaAs/InAlAs (*left*) and an InGaAsP/InGaAsP (*right*) electroabsorption modulator at several bias voltages. (After [37.50] with permission)

energies just below the band gap become more strongly absorbed when a field is applied, leading to a decrease in light intensity. Electroabsorption modulators can benefit enormously from the use of multiple quantum wells, where the electroabsorption effect is more than one order of magnitude greater than that in comparable bulk structures.

In quantum wells the modulation of the energy levels by an electric field applied perpendicular to the plane of the wells is called the quantum-confined Stark effect (QCSE). For a given applied voltage, it causes more change, $\Delta\alpha$, to the absorption coefficient α close to the band edge than in equivalent bulk structures for three main reasons. Due to the quantum confinement, there is a step-like increase in the density of states at the band edges, as described above, and so a faster rate of increase in absorption coefficient with energy. Thus, $\Delta\alpha/\Delta E_g$, the change in absorption coefficient with band gap, is larger. Secondly, the steep rise in the absorption coefficient with energy at the band edge is further enhanced in quantum well structures due to excitonic effects. An exciton consists of an electron–hole pair bound together by electrostatic attraction and has associated with it a sharp line absorption spectrum which is superimposed on the quantum well absorption. Figure 37.23 shows the measured photocurrent spectra at low temperature as a function of the applied reversed bias for two long-wavelength modulator structures. The exciton peak is clearly visible at the absorption edge, particularly for low bias values. Excitons also exist in bulk material at low temperatures but not at room temperature. In quantum wells however, the electrons and holes are confined

Fig. 37.24a,b The band alignment of a QW in (a) flat band (zero field) where the optical gap equals $E_g^t > h\nu$ (transparent) and (b) for a large field across the QW, where the optical gap equals $E_g^0 < h\nu$ (opaque)

into the same region of space by the well and so the electrostatic binding energy is sufficiently large that they are still able to exist at room temperature. Finally, the actual energy of the band edge is largely determined by the effect of quantum confinement, which depends not only on the width of the quantum well but also on its shape. Since the shape of the well can be strongly modified by an applied electric field, so can the electronic energies at the band edges, as can be seen from the shift in absorption edge with applied bias in Fig. 37.23. Thus ΔE_g is enhanced by quantum confinement.

The effect of an electric field applied perpendicular to the plane of a quantum well is to change the shape of the well from the rectangular well shown in Fig. 37.24a to the triangular shape shown in Fig. 37.24b. Solutions to the Schrödinger equation show that the lowest confined states are closer together in the triangular situation than the rectangular one and so the effective absorption edge is moved to lower energies. Because the electron ground state is shifted towards one side of the quantum well, and the hole ground state towards the opposite side, the overlap of the electron and hole wavefunctions is decreased by the application of an electric field. The result is to decrease the absolute value of the absorption coefficient and to decrease the exciton absorption peak, as seen in Fig. 37.23. However, if one considers an energy just below the band-edge exciton energy at zero field, at about 850 meV in Fig. 37.23, the absorption coefficient at that energy can be greatly increased by the application of an electric field.

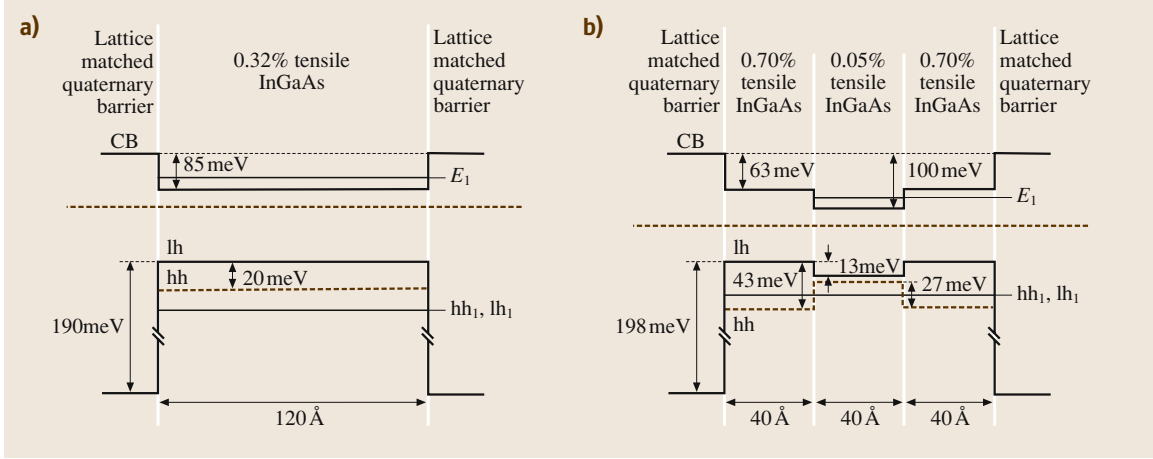

Fig. 37.25a,b Calculated conduction- and valence-band profiles for (a) conventional tensile QW and (b) multi-strain-stepped QW (After [37.51])

For a modulator, a very important parameter is the ratio of the light intensity transmitted in the *on* state to that transmitted in the *off* state when the field is applied. This is given simply by

$$P = \exp(\Delta\alpha L), \quad (37.38)$$

where L is the distance the light travels through the absorbing medium. In quantum well structures, although $\Delta\alpha$ is relatively large, if the light travels in a direction perpendicular to the plane of the wells, the length L is small; of the order of tens of nm. One way to overcome this problem is to use the QCSE modulator in the waveguide configuration; i. e. to pass the light parallel to the plane of the quantum wells in a waveguide structure similar to that for a laser as described previously. In this case the effective absorption per unit length will be decreased by the optical confinement factor (Γ) to $\Gamma\alpha$, but L can easily be increased much more; to tens or even hundreds of μm . Such a waveguide configuration can achieve a large on/off ratio but it has two potential problems. Firstly, it can have a large insertion loss because it is difficult to launch the light into the waveguide unless it is integrated with the laser source and also there can be light scattering and absorption along the length of the guide even in the on state. Secondly, the modulator will be dependent on the polarisation of the light beam travelling along the waveguide, as described below.

37.5.2 Polarisation-Insensitive Modulators

As was explained when considering strained-layer electronic properties, the degeneracy of the heavy- and

light-hole bands, which exists in bulk material, is split by confinement effects in a quantum well. This is because the quantum confinement energy is proportional to l/m^* and so the first light-hole valence band lh_1 lies below the first heavy-hole valence band hh_1 . As a consequence, the wavefunctions that make up the edge of the valence band are derived from the heavy-hole band and so only interact with TE-polarised photons as described above. Thus, while photons of energy close to the band edge and polarised in the TE mode are modulated as the band edges move together with applied electric field, photons of the same energy but polarised in the TM mode, are relatively unaffected. This is in general unacceptable if the photons are arriving from a system, such as an optical fibre, which may deliver photons of any polarisation in a manner which is sensitive to extraneous influences.

The problem of polarisation sensitivity in modulators, as with the polarisation-insensitive amplifier, may be dealt with by engineering the band structure with a judicious use of in-built strain within the quantum wells. As described above, the light-hole band may be raised in energy with respect to the heavy-hole band by the introduction of tensile strain. Thus, with tensile strain it is possible to shift the heavy- and light-hole bands until the confined states are once again degenerate, as shown in Fig. 37.25a. Such a system, although it may be polarisation insensitive at zero net field, can again become polarisation sensitive as a net field is applied, as is shown by the movement of the band edges in Fig. 37.26a. This effect arises since the heavy-hole confined level, being closer to its band edge, is more sensitive to the distortion of that band edge by the applied field. Once again, how-

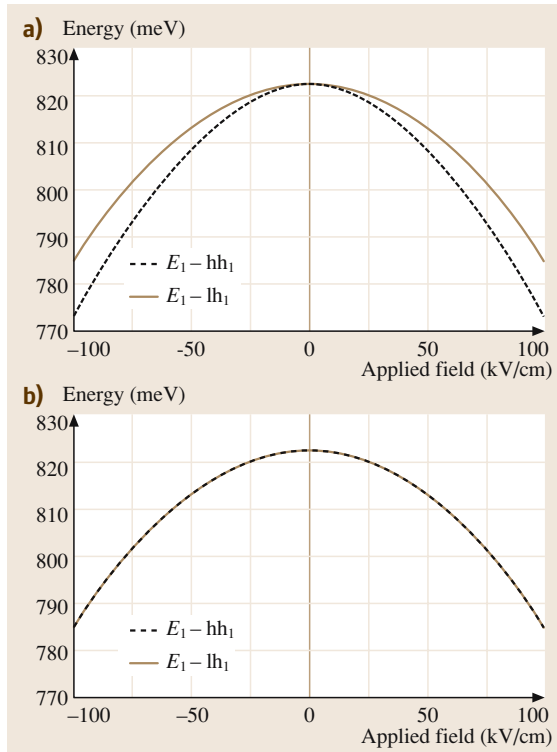

Fig. 37.26a,b Calculated quantum confined Stark shifts of the $E_1 - hh_1$ (dashed lines) and $E_1 - lh_1$ (solid lines) transitions for structures (a) and (b) in Fig. 37.25. (After [37.51])

ever, it is predicted that this effect can be compensated by further band-structure refinements brought about by employing three zones of different strain within the same well. This is illustrated in Fig. 37.25b. In this multi-strain well, the tensile strain is larger in the outer thirds of the well. Thus, when a field is applied and the hole wavefunctions are moved towards the edge of the well, the heavy-hole level sees a smaller effective well width and its change in energy can be made the same as for the light hole. Figure 37.26b shows that excellent matching of the movements of the heavy- and light-hole bands can be achieved with the three-zone well over the full range of practical electric fields, up to 100 kV/cm.

37.5.3 High-Speed High-Power QCSE Modulators

Strained-layer QCSE modulators have been successfully integrated with strained-layer lasers to produce high-speed low-chirp sources operating at 1.55 μm for optical communications. The laser and the modulator

Fig. 37.27a,b Calculated valence-band edge energies and band alignments for (a) lattice-matched modulator and (b) strained modulator, as in Fig. 37.28. The thick horizontal lines indicate the highest hh confined state

consist of the same wave-guide structure but are used in forward and reverse bias respectively. In this case there are no polarisation problems because if, for example, compressively strained wells are used the laser will produce the TE-polarised output, which is efficiently modulated by the modulator. One problem that is encountered, however, is that while the modulator is in the absorbing state a significant density of photogenerated carriers may accumulate in the quantum wells. This has two effects. Firstly, the carriers tend to fill the band-edge states, thus reducing the field in the well, and in addition bleaching the absorption process. Secondly, they may take a long time to escape, so that efficiency of switching to the nonabsorbing state is dependent on how long the modulator was absorbing and what carrier density had accumulated. In practice it is found that the escape rate of photogenerated holes from the quantum wells is slower than that for electrons and is the limiting process. This problem may be addressed by changing from the standard InGaAsP material system to InGaAlAs, which has a much smaller valence-band offset than in the equivalent InGaAsP layers [37.50]. Alternatively, the problem may be reduced by band-structure engineering in InGaAsP using strain.

Figure 37.27a shows the valence-band structure of a lattice-matched InGaAsP-based electroabsorption modulator designed to operate around 1.5 μm . The heavy-hole well was calculated to be 166 meV deep, and the structure showed power saturation, as illustrated by the open squares in Fig. 37.28. However, when a 1% compressive strain was introduced into the well and 1% tensile strain into the barriers between the wells, the calculated excitation energy from the heavy-hole states in the well to light-hole states in the barrier was reduced to 63 meV, as illustrated in Fig. 37.27b. Since the strain in the barrier has little effect on the well depth for heavy holes, the heavy-hole wavefunctions and quan-

Fig. 37.28 Total power absorbed in lattice-matched (*open squares*) and strained (*closed squares*) electroabsorption modulator as a function of power in the input fibre. (After [37.52] with permission)

tum confined Stark effect should be comparable in both structures, but now thermal excitation out of the well by phonon scattering to the light-hole level in the barrier is greatly enhanced. The improvement in the power-saturation characteristics of the strained modulator are shown by the solid squares in Fig. 37.28; a considerable improvement in the 10-GHz switching performance was also observed.

37.5.4 The Electro-Optic Effect

The real part of the refractive index can be described in terms of virtual transitions between the valence and conduction band and is therefore related to the imaginary part of the refractive index. Hence, when an electric field applied to a semiconductor leads to a change in the absorption characteristics as described above, there is also

Fig. 37.29 Schematic of a Mach-Zender interferometer

an accompanying change in the real part of the refractive index. This results in a phase change of the light reaching the end of the active region of the modulator. Whilst this causes unwanted chirp in the electroabsorption modulators described above, it can be used to advantage in modulators and switches that employ interference effects. A good example of such a device is the modulator based on a Mach-Zender interferometer. In this structure the incoming wave is divided into two equal components at a Y-junction and then recombined at a similar junction, as shown in Fig. 37.29. If the two arms of the interferometer are exactly equivalent then the two beams will arrive in-phase and constructively recombine at the output. However, if the refractive index for light travelling down one path is increased by the electro-optic effect so that its phase at the output is changed by π , then the two beams will destructively interfere at the output and no light will be transmitted. Band-structure considerations for the electro-optic effect are ones with which we are already familiar. The line-width enhancement factor α_1 is defined by

$$\alpha_1 = -\frac{4\pi}{\lambda} \left(\frac{\frac{dN}{dg}}{\frac{dg}{dn}} \right) \quad (37.39)$$

and provides a measure of the ratio of the change in the real part N of the refractive index to the change in the imaginary part g of the refractive index, each as a function of carrier density n . Thus, for modulators based on the electro-optic effect, we would wish to have a band structure that results in a large α_1 , while for electroabsorption modulators we require α_1 to be as small as possible.

37.6 Photodetectors

In the first part of this chapter we dealt with optoelectronic devices designed to produce light for use in applications including displays, indicators, data storage and communications. The latter two of these applications also require the ability to detect the light once it

has been created. Much of the explosion of interest in semiconductor optoelectronic devices over the past 20 or so years has been particularly aimed at the communications market. This has put high demands on the ability to detect small optical signals being transmitted at very

fast data rates (> 40 Gbit/s). In this section, we consider the important aspects for detectors and describe some of the approaches that have been used.

37.6.1 Photodetector Requirements

There are many attributes important to the design of photodetectors. These can broadly be split into the following categories: sensitivity, speed, noise, physical size (footprint), reliability, temperature sensitivity, ease of use and finally cost. When deciding on a particular photodetector one must decide which of these factors is of most importance to the particular application of interest.

37.6.2 Photodetection Theory

The primary requirement of the band structure of semiconductor optical detectors is that the band gap of the active region is less than the photon energy to be absorbed. The electron-hole pair formed when the photon is absorbed is then separated by an applied or built-in field that exists in the active region. If, under the influence of the field, the electron and hole move apart by a distance, x , then the charge induced to flow in the external circuit connected to the detector is x/l . In a simple photoconductive detector consisting of a bulk semiconductor with conducting electrodes, l is the distance between the electrodes. In a p-n or p-i-n diode detector, l is the width of the depletion region.

Several factors need to be taken into account when considering the band structure of a detector. Firstly, the absorption depth of the light to be detected must be matched to the width of the active region, so that there is a high probability that the photogenerated carriers will be produced within the active region or less than the

minority-carrier diffusion length from it. Figure 37.30 shows the absorption coefficient as a function of energy for direct-gap GaAs and for indirect-gap Si. An absorption coefficient of 10^3 cm^{-1} , typical for Si, corresponds to an absorption depth of $10 \mu\text{m}$, while 10^4 cm^{-1} for GaAs corresponds to a $10\text{-}\mu\text{m}$ absorption depth. One must also consider the effect of the band structure on the dark current in the device, since this sets the lower limit on the strength of the signal that can be detected. There are three important effects that can give rise to the generation of electron-hole pairs even when no light is falling on the device. These are: a) thermal generation, b) band-to-band tunnelling and c) avalanche breakdown. Processes (a) and (b) are illustrated in Fig. 37.31. Thermal generation, which occurs even at zero electric field, can itself be conveniently divided into two parts. Firstly there is the part i_{diff} due to the diffusion of minority carriers into the field region. Secondly there is the current i_{gr} due to thermal generation within the field region. The thermal generation current increases strongly with temperature but is relatively independent of applied field, although i_{gr} increases slightly with reverse bias since this causes the depletion width to increase. Process (b), band-to-band tunnelling, is indicated by the horizontal arrow i_t in Fig. 37.31. At large reverse fields, electrons at the top of the valence band see a triangular-shaped potential barrier through which it is possible for them to tunnel into the conduction band. This quantum-mechanical tunnelling is relatively independent of temperature but is strongly dependent on the applied field. Process (c), avalanche breakdown, which occurs at very large electric fields, has to be avoided except in avalanche photodetectors, which will be described in some detail below. Avalanche breakdown involves carriers with initial ki-

Fig. 37.31 Mechanisms contributing to the dark current in a reverse-biased p-i-n diode. Thermal generation has contributions from diffusion of minority carriers into the field region i_{diff} and from thermal generation within the field region i_{gr} . Zener (band-to-band) tunnelling is indicated by the horizontal arrow i_t

netic energies greater than the band-gap energy E_g away from the conduction-band minimum. This means that electrons in wide-band-gap III–V semiconductors will be at energies such that they are scattering between the central Γ minimum, the three X minima at the edges of the Brillouin zone in the $\langle 100 \rangle$ directions and the four L minima at the edges of the Brillouin zone in the $\langle 111 \rangle$ directions. Hydrostatic pressure measurements [37.53] showed that the effective ionisation energy $\langle E \rangle$ could be related to the average conduction-band energy simply by

$$\langle E \rangle = \frac{1}{8} (E_\Gamma + 3E_X + 4E_L) \quad (37.40)$$

where E_Γ , E_X and E_L are the energies of the Γ , X and L minima above the top of the valence band, respectively.

The first two effects giving rise to a dark current, described in (a) and (b) above, increase almost exponentially with decreasing band gap E_g . Therefore there exists an optimum value for the band gap E_g to be used to detect photons of a particular energy E_{ph} . Considering E_g to be the adjustable parameter, which can be determined by the alloy composition, as E_g is reduced below E_{ph} the absorption coefficient increases and light becomes more efficiently absorbed within the active region of the diode. However, once all the photons are absorbed, reducing E_g further adds nothing to the photocurrent but does continue to increase the dark current. Therefore, it is clear that the optimum band gap is just below that of the photon energy to be detected. The exact difference $E_{ph} - E_g$ depends upon the shape of the absorption edge of the material, the thickness of the active region and its position within the device.

37.6.3 Detectors with Internal Gain

In a photoconductive detector, gain can actually be achieved by adding impurities that trap one type of carrier, forming a centre with a low capture cross section for the other type of carrier. Assuming the trapped carrier is a hole, as the free electron reaches the anode another will be injected from the cathode and this process will continue until an electron recombines with the trapped hole. Under these circumstances x exceeds l and a gain of x/l is achieved: $x/l = \tau_r/t_t$, where t_t is the transit time of the electron between the electrodes and τ_r is the electron–hole recombination lifetime. The response time of such a system is $\tau_r = t_t x/l$ so that, as the gain increases, the speed of the device decreases. A related effect is obtained in a phototransistor. If, for example, we consider a photon being absorbed in the base or col-

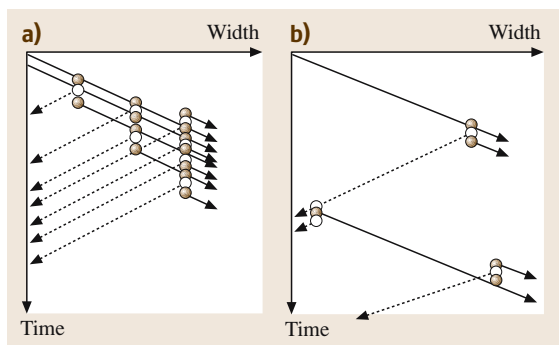

Fig. 37.32a,b Avalanche multiplication as a function of position and time where (a) the electron multiplication rate (solid line) is much greater than that for holes (dashed line). (b) when the electron and hole multiplication rates are equal, the current pulse continues for a long time

lector region of an n–p–n transistor then the presence of the hole, which will be effectively trapped in the base region, will cause the transit of electrons between the emitter and collector for the recombination lifetime of the hole. The gain of the system is then equal to the gain of the transistor, which is related to τ_r/t_t , where t_t is now the transit time of the electron from emitter to collector.

37.6.4 Avalanche Photodetectors

Interestingly, silicon as well as direct-band-gap materials can be used to produce efficient detectors, but for different reasons. In the direct-band-gap materials, photons with energies greater than the band gap are strongly absorbed by the creation of electron–hole pairs, leading to the generation in the detector of a primary photocurrent or photovoltage. In silicon, photons with energies just above the band gap are relatively weakly absorbed but the electrons generated can be greatly amplified by the process of avalanche multiplication. This occurs when a large reverse voltage is applied to the p–n or p–i–n junction of the detecting diode. Electrons drifting in the field can gain kinetic energy in excess of the band-gap energy E_g . It is then possible for the hot carrier to give up its energy and momentum in an impact ionisation process, resulting in the generation of an electron–hole pair. The generated carriers can, in turn, drift in the electric field and themselves generate further carriers. The band structure of silicon is particularly well suited for avalanche multiplication since impact ionisation can occur for hot electrons with conservation of energy and momentum when the electron’s kinetic energy is almost exactly equal to E_g [37.54]. By contrast

a hot hole in silicon requires an energy close to $3E_g/2$ before it can generate an electron–hole pair. Thus, in silicon, a large avalanche multiplication can be achieved with each electron that is optically generated and swept across the avalanche region. This situation is illustrated in Fig. 37.32a. Very large gains can be obtained but all of the carriers are swept out of the active region in a time equal or less than $t_e + t_h$, where t_e and t_h are the transit times taken by electrons and holes, respectively, to cross the active region.

In contrast, it is found that, in the majority of direct-band-gap materials, holes and electrons are able to produce impact ionisation at the same electric field. As a result, above this field, avalanching occurs for both types of carrier as they move in opposite directions and the carrier density escalates uncontrollably, leading to complete avalanche breakdown. This situation is illustrated in Fig. 37.32b. Gain, but also breakdown, occurs when the field is large enough to create an impact ionisation process just as the electron is about to leave the active region. If exactly the same happens for the hole, the situation can continue ad infinitum, leading to infinite gain but a current pulse that does not switch off. Of course, in fact, impact ionisation is a statistical process and the current pulse might stop after one electron transit or run away as described, leading to an unstable noisy detection system.

Silicon is therefore clearly a very useful material for the production of avalanche photodetectors (APDs). Unfortunately however, the detection bandwidth of silicon limits it from the visible spectrum up to $\approx 1\ \mu\text{m}$ in the near-infrared (IR). It is of significant technological importance to have fast high-gain low-noise detectors above this wavelength, in particular in the range $1.3\text{--}1.6\ \mu\text{m}$ for optical communications. The mid-infrared is also of importance due to the large number

of gas absorption bands in this range. Due to the effects discussed above, the performance of APDs in the near-mid-infrared region is poor when compared with silicon APDs. Recently, Adams proposed that APDs based upon InGaAsN may give rise to improved characteristics for detection in the near- and mid-IR [37.55]. As discussed earlier in this chapter, InGaAsN is already showing great promise for long-wavelength lasers due to the unusually large band-gap bowing brought about by small concentrations of nitrogen in GaAs. This clearly makes it a potential candidate for the manufacture of long-wavelength detectors. However, in addition to the large band-gap bowing, InGaAsN has an unusually large conduction-band effective mass derived from the dilute amount of nitrogen in the lattice. This has several effects of benefit to APDs. Firstly, the high effective mass inhibits electrons from gaining kinetic energy under an applied field. Secondly, the increased mass, and hence increased density of states, will increase the probability of electron scattering. As the electrons heat up and their energy approaches that of the N levels, they will be strongly scattered. Furthermore, if any electrons manage to reach the top of the E^- band, they have to be scattered across, or tunnel through, the energy gap to the next conduction (E^+) band before they can gain more energy. All of these effects prevent electrons from avalanching. However, since the valence band is largely unaffected by the presence of nitrogen, the holes may be accelerated by the field and avalanche. It has been proposed that such devices will have a multiplication of $\approx 10^4$ compared with < 10 in the best currently available APDs at these wavelengths. Furthermore, it is also predicted that the noise factor of these devices could be reduced by two orders of magnitude. Although yet to be demonstrated in practice, InGaAsN may in the future provide both high-quality detectors as well as emitters in the infrared.

37.7 Conclusions

This chapter introduced some of the most important optoelectronic devices in use today. It has discussed how these devices were developed based upon highly innovative work which has transformed semiconductor growth technology over the past 40 years. The requirements for lasing action in semiconductors were discussed as well as the ways in which

low-dimensional structures and strain may be used to improve the properties of devices such as lasers (both edge-emitting and surface-emitting), modulators, amplifiers and detectors. The chapter considered current state-of-the-art semiconductor laser devices and discussed emerging future directions in semiconductor optoelectronics.

Liquid Crystal

38. Liquid Crystals

This chapter outlines the basic physics, chemical nature and properties of liquid crystals. These materials are important in the electronics industry as the electro-optic component of flat-panel liquid-crystal displays, which increasingly dominate the information display market.

Liquid crystals are intermediate states of matter which flow like liquids, but have anisotropic properties like solid crystals. The formation of a liquid-crystal phase and its properties are determined by the shape of the constituent molecules and the interactions between them. While many types of liquid-crystal phase have been identified, this Chapter focuses on those liquid crystals which are important for modern displays.

The electro-optical response of a liquid crystal display depends on the alignment of a liquid-crystal film, its material properties and the cell configuration. Fundamentals of the physics of liquid crystals are explained and a number of different displays are described.

In the context of materials, the relationship between the physical properties of liquid crystals and their chemical composition is of vital importance. Materials for displays are mixtures of many liquid-crystal compounds carefully tailored to optimise the operational behaviour of the display. Our current understanding of how chemical structure determines the physical properties is outlined, and data for typical liquid-crystal compounds are tabulated. Some key

38.1 Introduction to Liquid Crystals

Liquid crystals have been known for almost 120 years but it is only in the last 30 years or so that their unique application in display devices has been recognised. Now they are seen as extremely important materials having made possible the development of thin screens for use with personal computers (PCs) and in televisions. In

fact a wide range of different liquid-crystal (LC) display devices has been developed. The common feature for each of these is that the optical characteristics of the display are changed on application of an electric field across a thin liquid-crystal film. The process causing this change is associated with a variation in the

macroscopic organisation of the liquid crystal within the cell. The liquid crystal is, therefore, strictly behaving as a molecular material and not an electronic one. Nonetheless the display itself is closely integrated with electronic components. Since liquid crystals may be unfamiliar to those concerned with conventional electronic materials, this section begins with an introduction to liquid crystals and the compounds that form them. The following section describes the basic physics for liquid crystals which are needed to understand their use in display devices. The functioning of the most important displays is described in Sect. 38.3, which makes contact with the basic physics outlined in Sect. 38.2. The liquid crystal materials used in display devices are discussed in the final section, where the necessary optimisation of a wide range of properties is addressed.

The majority of chemical compounds can exist in three states of matter, namely crystal, liquid or gas, each with its defining characteristics. There is a fourth state known as a liquid crystal and, as the name suggests, this state has characteristics of both crystals and liquids. Thus a liquid crystal flows when subject to a stress, like a liquid, but certain of its properties are anisotropic, like a crystal. This macroscopic behaviour, often used to identify the phase, implies that at the microscopic or molecular level the material has an element of long-range orientational order together with some translational disorder at long range. It is this combination of order and disorder that makes liquid

crystals so fascinating and gives them their potential for applications, especially in the field of electro-optic displays.

A variety of different classes of materials are known to form liquid crystals at some point on their phase diagram [38.1]. These include organic materials where the liquid crystal is formed, on heating, between the crystal and isotropic liquid phases. Such materials are known as thermotropic liquid crystals and are the subject of this Chapter. Another class is formed by amphiphilic organic materials in which part of the constituent molecules favours one solvent, normally water, while the other part does not. When the amphiphile is dissolved in the water, the molecules form aggregates which then interact to give the liquid-crystal phase, the formation of which is largely controlled by the concentration of amphiphile. These are known as lyotropic liquid crystals; they underpin much of the surfactant industry, although they are not used in displays and so will not be considered further. Colloidal dispersions of inorganic materials such as clays can also form liquid-crystal phases depending on the concentration of the colloidal particles. Solutions of certain organic polymers also exhibit liquid-crystal phases and, like the colloidal systems, the solvent acts to increase the separation between polymer chains but does not significantly affect their state of aggregation. A prime example of such a system is the structural polymer Kevlar, which for the same weight is stronger than steel; it is formed by processing a nematic solution of the polymer.

Fig. 38.1 The molecular structures for a selection of compounds which form calamitic liquid crystals

The following sections return to thermotropic liquid crystals and describe the molecular organisation within the phases, mention some of their properties and briefly indicate the relationship between the phase and molecular structures.

38.1.1 Calamitic Liquid Crystals

In view of the anisotropic properties of liquid crystals, it seems reasonable that a key requirement for their formation is that the molecules are also anisotropic. This is certainly the case, with the majority of liquid crystals having rod-like molecules, such as those shown in Fig. 38.1. One of the simplest nematogenic rod-like molecules is *p*-quinquephenyl (Fig. 38.1a), which is essentially rigid. However, flexible alkyl chains can also be attached at one or both ends of the molecule (Fig. 38.1b and c) or indeed in the centre of the molecule (Fig. 38.1d), and rigid polar groups such as a cyano (Fig. 38.1d–f) may be attached at the end of the molecule. The rigid part is usually constructed from planar phenyl rings (Fig. 38.1a–e) but they can be replaced by alicyclic rings (Fig. 38.1f) which enhance the liquid crystallinity of the compound. The term calamitic, meaning rod-like, is applied to the phases that they form. There are, in fact, many different calamitic liquid-crystal

phases but we shall only describe those which are of particular relevance to display applications.

At an organisational level the simplest liquid crystal is called the nematic and in this phase the rod-like molecules are orientationally ordered, but there is no long-range translational order. A picture showing this molecular organisation, obtained from a computer simulation of a Gay–Berne mesogen [38.2] is given in Fig. 38.2b. The molecular shape is ellipsoidal and the symmetry axes of the ellipsoids tend to be parallel to each other and to a particular direction known as the director.

In contrast there is no ordering of the molecular centres of mass, except at short range. The essential difference between the nematic and isotropic phases (Fig. 38.2a) is the orientational order, which is only short range in the isotropic liquid. At a macroscopic level the nematic phase is characterised by its high fluidity and by anisotropy in properties such as the refractive index. The anisotropic properties for a nematic have cylindrical symmetry about the director, which provides an operational definition of this unique axis and is the optic axis for the phase. The anisotropy in the refractive index combined with the random director distribution results in the turbidity of the phase, which contrasts with the transparency of the isotropic liquid. This on its own would not be sufficient to identify the liquid crystal as a nematic phase but identification is possible from the optical texture observed under a polarising microscope. These textures act as fingerprints for the different liquid-crystal phases. An example of such a texture for a nematic phase is shown in Fig. 38.3a; it is created by the anisotropy or birefringence in the refractive index combined with a characteristic distribution of the director in the sample.

The next level of order within liquid crystal phases is found for the smectic A phase. Now, in addition to the long-range orientational order, there is translational order in one dimension, giving the layered structure shown in Fig. 38.2c [38.2]. The director associated with the orientational order is normal to the layers. Within a layer there is only short-range translational order as in a conventional liquid. In this structure the layer spacing is seen to be comparable but slightly less than the molecular length, as found experimentally for many smectic phases.

At a macroscopic level the layer structure means that the fluidity of a smectic A phase is considerably less than for a nematic phase. The properties are anisotropic and the birefringence is responsible for the turbidity of the phase, as found for a nematic. However, under a polar-

Fig. 38.2a–c The molecular organisation in (a) the isotropic phase (b) the nematic phase and (c) the smectic A phase obtained from the simulation of a Gay–Berne calamitic mesogen

Fig. 38.3a–c Typical optical textures observed with a polarising microscope for (a) nematic, (b) smectic A and (c) columnar liquid-crystal phases

ising microscope the optical texture is quite different to that of a nematic, as is apparent from the focal conic fan texture shown in Fig. 38.3b.

A variant on the smectic A is the smectic C phase. The essential difference to the smectic A phase is that the director in that smectic C phase is tilted with respect to the layer normal. The defining characteristic of the smectic C phase is then the tilt angle, which is taken as the angle between the director and the layer normal. This tilt in the structure reduces the symmetry of the phase to the point group C_{2h} in contrast to $D_{\infty h}$ for nematic and smectic A phases. This lowering in symmetry naturally influences the symmetry of the properties. The fluidity of the smectic C phase is comparable to that of a smectic A phase. However, the optical texture can be quite different and it has elements similar to a nematic phase and to a smectic A; the focal conic fan structure is less well defined and is said to be broken. The nematic-like features result from the fact that the tilt direction of the director is not correlated between the smectic layers and so it adopts a distribution analogous to that of the director in a nematic phase.

The molecular factors which influence the ability of a compound to form a liquid-crystal phase have been well studied both experimentally [38.3] and theoretically [38.4]. Consider the simple nematic as formed, for example, by *p*-quinquephenyl (Fig. 38.1a); this melts at 401 °C to form the nematic phase, which then undergoes a transition to the isotropic phase at 445 °C; the transition temperatures are denoted by T_{CrN} and T_{NI} , respectively. The very high value of T_{NI} , which is a measure of the stability of the nematic phase, is attributed to the large length-to-breadth ratio of *p*-quinquephenyl. In contrast *p*-quaterphenyl, formed by the removal of just one of the five phenyl rings, does not exhibit a liquid-crystal phase at atmospheric pressure, even though its shape anisotropy is still relatively large. This occurs be-

cause, on cooling, the isotropic liquid freezes before the transition to the nematic phase can occur. Indeed many compounds with anisotropic molecules might be expected to form liquid-crystal phases, but do not because of their high melting points. As a consequence the molecular design of liquid crystals needs to focus not only on increasing the temperature at which the liquid crystal–isotropic transition occurs but also on lowering the melting point. One way by which this can be achieved is to attach flexible alkyl chains to the end of the rigid core (Fig. 38.1). In the crystal phase the chain adopts a single conformation but in a liquid phase there is considerable conformational disorder, and it is the release of conformational entropy on melting that lowers the melting point. The addition of the chain also affects the nematic–isotropic transition temperature, which alternates as the number of atoms in the chain passes from odd to even. This odd–even effect is especially dramatic when the flexible chain links two mesogenic groups (Fig. 38.1d) to give what is known as a liquid-crystal dimer [38.5]. The odd–even effect is particularly marked because the molecular shapes for the dimers with odd and even spacers differ significantly on average, being bent and linear, respectively.

The attachment of alkyl chains to the rigid core of a mesogenic molecule has another important consequence, as it tends to promote the formation of smectic phases (Fig. 38.1b and c). The reason that the chains lead to the formation of such layered structures is that, both energetically and entropically, the flexible chains prefer not to mix with the rigid core, and so by forming a layer structure they are able to keep apart. Indeed it is known that biphenyl (a rigid rod-like structure) is not very soluble in octane (a flexible chain). The lack of compatibility of the core and the chain increases with the chain length and so along a homologous series it is those members with long alkyl

chains that form smectic phases. For example, 4-pentyl-4'-cyanobiphenyl (Fig. 38.1e) forms only a nematic phase whereas the longer-chain homologue, 4-decyl-4'-cyanobiphenyl only exhibits a smectic A phase. To obtain a tilted smectic phase such as a smectic C there clearly needs to be a molecular interaction which favours an arrangement for a pair of parallel molecules that is tilted with respect to the intermolecular vector. Such a tilted structure can be stabilised by electrostatic interactions; for example by off-axis electric dipoles (Fig. 38.1b and c) [38.6] or with a quadrupolar charge distribution.

The ability of a compound to form a liquid crystal is not restricted to just one phase. The delicate balance of the intermolecular interactions responsible for the various liquid-crystal phases means that transitions between them can result from modest variations in temperature. This is apparent for the 4,4'-dialkyl-2',3'-difluoroterphenyl shown in Fig. 38.1c, which on cooling the isotropic liquid forms nematic, smectic A and smectic C phases; such a compound is said to be polymorphic. Materials which form even more liquid-crystal phases are known [38.1]. The occurrence of several liquid-crystal phases in a single system can be of value in processing the material for display applications.

38.1.2 Chiral Liquid Crystals

The mesogenic molecules that have been considered so far are achiral in the sense that the molecule is superimposable on its mirror image. Molecules may also be

chiral in that they are not superimposable on their mirror images; this chirality can result from the tetrahedral arrangement of four different groups around a single carbon atom. This is illustrated in Fig. 38.4a which shows such an arrangement together with its mirror image; these are known as enantiomers. The presence of a chiral centre will certainly change the nature of the interactions between the molecules and it is relevant to see whether the chiral interactions might not influence the structure of the liquid-crystal phases exhibited by the material. From a formal point of view it might be expected that the molecular chirality of a mesogen should be expressed through the symmetry of the liquid-crystal structure. This proves to be the case, provided no other interactions oppose the chiral deformation of the liquid-crystal phase. In fact the first liquid crystal to be discovered [38.7] was chiral; this was cholesteryl benzoate where the cholesteryl moiety contains many chiral centres. The structure of the liquid crystal is nematic-like in that there is no long-range translational order but there is long-range orientational order. However, the difference between this phase and a nematic formed from achiral materials is that the director is twisted into a helix. The helix may twist in a left-handed or a right-handed sense and these structures, shown in Fig. 38.4b, are mirror images of each other. The phase structure is certainly chiral and so is known as a chiral nematic, although originally it was called a cholesteric phase. The symbol for the phase is N^* , where the asterisk indicates that the phase has a chiral structure.

The helical structure is characterised by the pitch of the helix p which is the distance along the helix axis needed for the director to rotate by 2π . Since the directions parallel and antiparallel to the director are equivalent the periodicity of the chiral nematic is $p/2$. For many chiral nematics the helical pitch is comparable to the wavelength of visible light. This, together with the periodic structure of the phase, means that Bragg reflection from a chiral nematic will be in the visible region of the spectrum and so this phase will appear coloured with the wavelength of the reflected light being related to the pitch of the helix. This pitch is sensitive to temperature, especially when the chiral nematic phase is followed by a smectic A. This sensitivity has been exploited in the thermochromic application of chiral nematics, where the reflected colour of the phase changes with temperature [38.1].

The chirality of cholesteryl benzoate clearly results from the chiral centres present in the mesogenic molecule. However, the chirality can also be introduced

Fig. 38.4 (a) A chiral mesogenic molecule, (R) 2-[4'-cyano-4-biphenyl]-hexane, together with its mirror image, (S) 2-[4'-cyano-4-biphenyl]-hexane. (b) The left- and right-handed helical organisation of the director for a chiral nematic

indirectly to a mesogen by simply adding a chiral dopant, which does not need to be mesogenic. The mixture will be chiral and this is sufficient to lead to a chiral nematic. The pitch of this mixture depends on the amount of the dopant and the inverse pitch, p^{-1} , proves to be proportional to its concentration. The handedness of the helix induced by the dopant will depend on its stereochemical conformation and will be opposite for the two enantiomers. Accordingly, if both enantiomers are present in equal amounts, i. e. as a racemic mixture, then doping a nematic with this will not convert it to a chiral nematic.

Chiral smectic phases are also known in which the director adopts a helical structure as a result of introducing molecular chirality into the material either as a dopant or as an intrinsic part of the mesogenic molecule. The chiral smectic C phase, denoted SmC^* , provides an appropriate example with which to illustrate the structure of such phases. In an achiral smectic C phase the tilt direction of the director changes randomly from layer to layer, analogous to the random director orientation in an achiral nematic. For the chiral smectic C phase, as might be anticipated, the tilt direction of the director rotates in a given sense, left-handed or right-handed, and by a small, fixed amount from layer to layer. Other structural features of the smectic C phase remain unchanged. Thus, the director of the chiral smectic C phase has a he-

lical structure with the helix axis parallel to the layer normal. The pitch of the helix is somewhat smaller than that of the associated chiral nematic phase. The magnitude of the pitch is inversely related to the tilt angle of the smectic C, and since this grows with decreasing temperature so the pitch decreases. The reduced symmetry, C_2 , of the SmC^* phase leads to the introduction of a macroscopic electrical polarisation [38.8]. This is of potential importance for the creation of fast-switching displays.

The ability of the SmC^* phase to adopt a helical structure results from the fact that the tilt direction for the director acts in an analogous manner to the director in a nematic, and importantly that the layer spacing is preserved in the helical structure. In marked contrast there are strong forces inhibiting the creation of a twisted structure for a smectic A composed of chiral molecules. The director is normal to the layers and so the creation of a twisted structure would require a variation in the layer thickness but this has a high energy penalty associated with it. Accordingly many of the smectic A phases formed from chiral molecules have the same structure as those composed of achiral molecules. There are, however, exceptions and these occur when the chiral interactions are especially strong and, presumably, the translational order of the layers is small. Under such

Fig. 38.5 A selection of molecular structures for compounds that form discotic liquid crystals

conditions the smectic A structure is partially destroyed, creating small SmA-like blocks about 1000 Å wide, separated by screw dislocations [38.9, 10]. These defects in the organisation allow the directions for the blocks to rotate coherently to give a chiral helical structure; the pitch of the helix is found to be larger than that in an analogous chiral nematic phase. This chiral phase is just one example of a liquid-crystal structure stabilised by defects; it is known as a twist grain-boundary phase and denoted by TGBA*. The letter A indicates that the director is normal to the layers in the small smectic blocks; there is a comparable phase in which the director is tilted, denoted by TGBC*.

38.1.3 Discotic Liquid Crystals

The key requirement for the formation of a liquid crystal is an anisotropic molecule, as exemplified by the rod-like molecules described in the previous sections. However, there is no reason why disc-like molecules should not also exhibit liquid-crystal phases. Nonetheless, it was not until 1977 that the first example of a thermotropic

liquid crystal formed from disc-like molecules was reported [38.11]. Since that time several liquid-crystal phases have been identified and these phases are known collectively as discotic liquid crystals. The range of compounds that exhibits these phases is now extensive and continues to grow [38.12], although it does not match the number that form calamitic liquid crystals. The molecular structures of three compounds which form discotic liquid crystals are shown in Fig. 38.5.

As for rod-like molecules, the simplest liquid-crystal phase formed by disc-like molecules is the nematic, usually denoted N_D , where the D indicates the disc-like nature of the molecules. Within the nematic phase, shown in Fig. 38.6a, the molecular centres of mass are randomly distributed and the molecular symmetry axes are orientationally correlated. The nematic structure is the same as for that formed from rod-like molecules, the only difference being that the symmetry axes which are orientationally ordered are the short axes for the discs and the long axes for the rods. The point symmetry of the discotic and calamitic nematic is the same, namely $D_{\infty h}$. The discotic nematic is recognised in the same way as the calamitic nematic; that is it flows like a normal fluid and its anisotropy is revealed by a characteristic optical texture analogous to that shown in Fig. 38.3a. In fact, the refractive index of a discotic nematic along the director is smaller than that perpendicular to it, which is the opposite to that for a calamitic nematic. It has been suggested that this difference may be of value in display devices [38.13] but this concept has not as yet been commercialised.

The other class of discotic liquid crystals possesses some element of long-range translational order and these are known as columnar phases, two examples of which are sketched in Fig. 38.6b and c. The disc-like molecules are stacked face-to-face into columns. A single column has a one-dimensional structure, and as such is not expected to exhibit long-range translational order, although this can result from interactions between neighbouring columns in the liquid-crystal phase. The column–column interactions will result in the columns being aligned parallel to each other; these interactions will also determine how the columns are packed. When the discs are orthogonal to the column axis the cross section is essentially circular and so the columns pack hexagonally, as shown in Fig. 38.6b. The symbol given to this phase is Col_{hd} , where h denotes hexagonal packing of the columns and d indicates that the arrangement along the column is disordered. The point group symmetry of this phase is D_{6h} . The disc-like molecules may also be tilted with respect to the column axis, giving

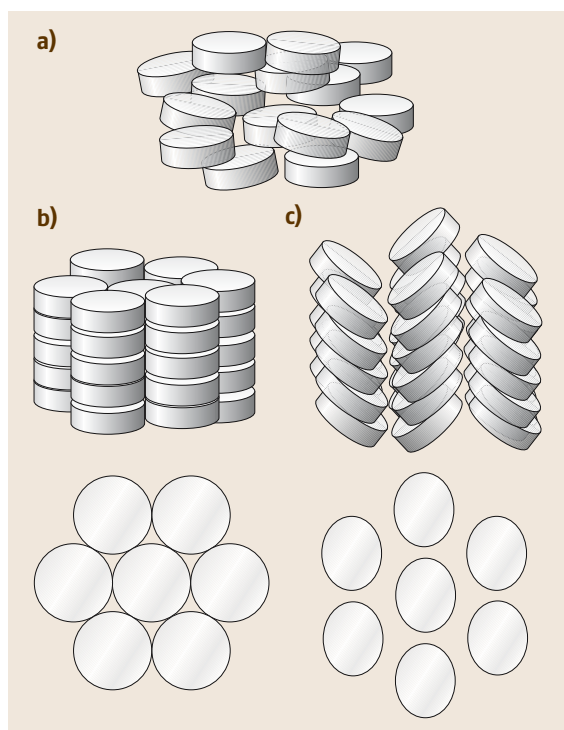

Fig. 38.6a–c The molecular organisation in discotic liquid-crystal phases, (a) nematic, (b) hexagonal columnar and (c) rectangular columnar

an elliptical cross section to the columns. As a result the columns are packed on a rectangular lattice; there are four possible arrangements and just one of these is indicated in Fig. 38.6c. In general the mnemonic used to indicate a rectangular columnar phase is Col_{rd}. The point group symmetry of the rectangular columnar phase is D_{2h} and the extent to which the structure deviates from that of the Col_{hd} phase will depend on the magnitude of the tilt angle within the column. The columnar phases can be identified from their optical textures and an example of one is shown in Fig. 38.3c.

The columnar phases have potential electronic applications because of the inhomogeneity of the molecules that constitute them; i.e. the central part is aromatic while the outer part is aliphatic. As a result of the overlap between the π -orbitals on the centres of neighbouring discs it should be possible for electrical conduction to take place along the core of the column. This should occur without leakage into adjacent columns because of the insulation provided by the alkyl chains. It should also be possible to anneal these molecular wires because of their liquid-crystal properties [38.14]. This and the ability to avoid defects in the columns which can prevent electronic conduction in crystals mean that the columnar phase has many potential advantages over non-mesogenic materials. In addition, discotic systems are also used as compensating films to improve the optical characteristics for some liquid-crystal displays.

At a molecular level the factors that are responsible for the formation of the discotic liquid-crystal phases are similar to those for calamitic systems. Thus, the molecular design should aim to increase the liquid

crystal–isotropic transition temperature while decreasing the melting point. The latter is certainly achieved by attaching flexible alkyl chains to the perimeter of the rigid disc. The creation of the columnar phases should be relatively straightforward provided the central core is both planar and large. Then, because of the strong attractive forces between the many atoms in the rigid core the molecules will wish to stack face-to-face in a column. The formation of the columns will also be facilitated by the flexible alkyl chains attached to the core. Clearly then it may prove to be difficult to create the nematic phase before the columnar phase is formed unless the disc–disc interactions can be weakened. One way in which this can be achieved is by destroying the planarity of the core, for example, by using phenyl rings attached to the molecular centre so that they can rotate out of the plane (Fig. 38.5a). It is to be expected that the columnar phases should occur below the nematic phase, corresponding to an increase in order with decreasing temperature. This is usually observed, for example, for the hexasubstituted triphenylenes (Fig. 38.5b). However, the truxene derivatives, with long alkyl chains on the perimeter, (Fig. 38.5c) exhibit quite unusual behaviour. For these compounds the crystal melts to form a discotic nematic and then at a higher temperature a columnar phase appears. This deviates from the expected sequence, and because the nematic phase appears at a lower temperature than the columnar phase it is usually referred to as a re-entrant nematic. The occurrence of a re-entrant phase is often attributed to a conformational change which strengthens the molecular interactions with increasing temperature thus making the more ordered phase appear at higher temperatures.

38.2 The Basic Physics of Liquid Crystals

38.2.1 Orientational Order

The defining characteristic of a liquid crystal is the long-range order of its constituent molecules. That is, for rod-like molecules, the molecular long axes tend to align parallel to each other even when separated by large distances. The molecules tend to be aligned parallel to a particular direction known as the director and denoted by \mathbf{n} . This is an apolar vector, that is $\mathbf{n} = -\mathbf{n}$, because the nematic does not possess long-range ferroelectric order. The properties of the nematic phase are cylindrically symmetric about the director, which provides a macroscopic definition of this. The anisotropy of the

properties results from the orientational order and the extent of this is commonly defined [38.15] by

$$S = \left\langle (3 \cos^2 \beta - 1) / 2 \right\rangle, \quad (38.1)$$

although other definitions are possible [38.16]. Here β is the angle made by a molecule with the director and the angular brackets indicate the ensemble average. In the limit of perfect order S is unity while in the isotropic phase S vanishes. The temperature dependence of S is shown in Fig. 38.7 for the nematogen, 4,4'-dimethoxyazobenzene; this behaviour is typical of most nematic liquid crystals. At low temperatures S is about 0.6 and then decreases with increasing

Fig. 38.7 The temperature variation of the orientational order parameter, S , for 4,4'-dimethoxyazobenzene; the different symbols indicate results determined with different techniques

temperature, reaching about 0.3 before it vanishes discontinuously at the nematic–isotropic transition, in keeping with the first-order nature of this transition. It is also found, both experimentally and theoretically, that the orientational order of different nematic liquid crystals is approximately the same provided they are compared at corresponding temperatures, either the reduced, T/T_{NI} , or shifted, $T_{\text{NI}} - T$, temperatures [38.16]. Since many properties of liquid crystals are related to the long-range orientational order these also vary with temperature especially in the vicinity of the transition to the isotropic phase.

38.2.2 Director Alignment

The director in a bulk liquid crystal is distributed randomly unless some constraint is applied to the system; a variety of constraints can be employed and two of these are of special significance for display applications. One of them is an electric field and because of the inherent anisotropy in the dielectric permittivity of the liquid crystal the director will be aligned. The electric energy density controlling the alignment is given by [38.17]

$$U_{\text{elec}} = -\varepsilon_0 \Delta\varepsilon (\mathbf{n} \cdot \mathbf{E})^2 / 2. \quad (38.2)$$

Here ε_0 is the permittivity of a vacuum and the scalar product $\mathbf{n} \cdot \mathbf{E}$ is $E \cos \theta$, where E is the magnitude of the field \mathbf{E} and θ is the angle between the director and the field, $\Delta\varepsilon$ is the anisotropy in the dielectric tensor

$$\Delta\varepsilon = \varepsilon_{||} - \varepsilon_{\perp}, \quad (38.3)$$

where the subscripts denote the values parallel ($||$) and perpendicular (\perp) to the director. If the dielectric anisotropy is positive then the director will be aligned parallel to the electric field and, conversely, if $\Delta\varepsilon$ is negative, then the director is aligned orthogonal to the field. The molecular factors that control the sign of $\Delta\varepsilon$ will be discussed in Sect. 38.4. Of course, intense electric fields are also able to align the molecules in an isotropic phase but what is remarkable about a nematic liquid crystal is the very low value of the field needed to achieve complete alignment of the director. Thus for a bulk nematic free of other constraints the electric field necessary to align the director is typically about 30 kV/m, although the value does clearly depend on the magnitude of the dielectric anisotropy. This relatively small value results because of the long-range orientational correlations which mean that the field acts, in effect, on the entire ensemble of molecules and not just single molecules.

The other constraint, essential for display devices, is the interaction between the director and the surface of the container [38.18]. At the surface there are two extreme arrangements for the director. One is with the director orthogonal to the surface, the so-called homeotropic alignment. In the other the director is parallel to a particular direction in the surface; this is known as the uniform planar alignment. The type of alignment depends on the way in which the surface has been treated. For example, for a glass surface coated with silanol groups a polar liquid crystal will be aligned homeotropically, while to achieve this alignment for a non-polar nematic the surface should be covered with long alkyl chains. In these examples the direct interaction of a mesogenic molecule with the surface produces an orthogonal alignment which is then propagated by the long-range order into the bulk. To achieve uniform planar alignment of the director the surface is coated with a polymer, such as a polyimide, which on its own would result in planar alignment. To force the director to be parallel to a particular direction in the surface the polymer is rubbed which aligns the director parallel to the direction of rubbing. There is still some uncertainty about the mechanism responsible for uniform planar alignment. It might result from alignment of the polymer combined with anisotropic intermolecular attractions with the mesogenic molecules, although it had been thought [38.19] to have its origins in surface grooves and the elastic interactions which are described later.

The energy of interaction between the surface and the director clearly depends on the nature of the surface treatment and the particular nematic. *Rapini* and

Popular [38.20] have suggested the following simple form for the surface energy density

$$U_S = -A(\mathbf{n} \cdot \mathbf{e})^2/2, \quad (38.4)$$

where A is the anchoring energy and \mathbf{e} is the easy axis or direction along which the director is aligned. Clearly it has an analogous form to that for the anisotropic interaction between the nematic and an electric field (38.2) but is essentially phenomenological. The anchoring energy is determined to be in the range 10^{-7} – 10^{-5} J/m² [38.21]. The upper value corresponds to strong anchoring in that typical values of the electric field would not change the director orientation at the surface. In contrast the lower value is associated with weak anchoring and here the director orientation at the surface can be changed by the field.

38.2.3 Elasticity

As the name suggests, a liquid crystal has some properties typical of crystals and others of liquids. The elastic properties of crystals should, therefore, be reflected in the behaviour of liquid crystals. Here it is the director orientation which is the analogue of the atomic positions in a crystal. In the ground state of a nematic liquid crystal the director is uniformly aligned. However, the elastic torques, responsible for this uniform ground state, are weak and, at temperatures within the nematic range, the thermal energy is sufficient to perturb the director configuration in the bulk. This perturbed state can take various forms depending on a combination of fac-

tors but, whatever the form, it can be represented as a sum of just three fundamental distortion modes. These are illustrated in Fig. 38.8 and are the splay, twist and bend deformations [38.22]. At a more formal level these modes are also shown in terms of the small deviations of the director from its aligned state at the origin as the location from this is varied. For example, for the twist deformation away from the origin along the x -axis there is a change in the y -component of the director, n_y , and the displacement along the y -axis causes a change in n_x . The magnitude of the twist deformation is measured by the gradients $\partial n_y/\partial x$ and $\partial n_x/\partial y$.

The energy needed to stabilise a given distortion of the director field is clearly related to the extent of the deformation via the gradients. This distortion energy density for a bulk nematic liquid crystal is given by continuum theory [38.22] as

$$f = \left[K_1(\nabla \cdot \mathbf{n})^2 + K_2(\mathbf{n} \cdot \nabla \times \mathbf{n})^2 + K_3(\mathbf{n} \times \nabla \times \mathbf{n})^2 \right]/2, \quad (38.5)$$

where the terms $\nabla \cdot \mathbf{n}$, $\mathbf{n} \cdot \nabla \times \mathbf{n}$ and $\mathbf{n} \times \nabla \times \mathbf{n}$ correspond to the splay, twist and bend deformations, respectively. The contribution each makes to the free energy is determined by the proportionality constants K_1 , K_2 and K_3 , which are usually known as the Frank elastic constants for splay, twist and bend, respectively. They are small, typically 5×10^{-12} N, and their small magnitude explains why the thermal energy is able to distort the uniform director arrangement so readily. The elastic constants are not in fact constant but vary with temperature

Fig. 38.8a–c The three fundamental deformations for the nematic director (a) splay, (b) twist and (c) bend

Fig. 38.9 The temperature dependence of the three elastic constants, K_1 , K_2 and K_3 , for the nematic 5CB

and nor are they equal as the results for 4-pentyl-4'-cyanobiphenyl (5CB) shown in Fig. 38.9 demonstrate. The twist elastic constant is seen to be the smallest while the largest is the bend elastic constant. This means that it is easiest to induce a twist deformation in a nematic while a bend deformation is the most difficult to create. All three elastic constants decrease with increasing temperature in keeping with the decreasing order as the transition to the isotropic phase is approached. Like the orientational order the elastic constants vanish discontinuously at the first-order nematic–isotropic transition.

The continuum theory is especially valuable in predicting the behaviour of display devices and this is illustrated by considering one of the ingenious experiments devised by *Fréedericksz* to determine the elastic constants [38.23]. In these a thin slab of nematic is confined between two glass plates with a particular director configuration, either uniform planar or homeotropic produced by surface forces. These forces control the director orientation just at the two surfaces and the alignment across the slab is propagated by the elastic interactions. A field is then applied which will move the director away from its original orientation and the variation of the director orientation with the field strength provides the elastic constant. To employ the continuum theory in order to describe the experiment it is necessary to add the field energy density (38.2) to the elastic free-energy density in (38.5). The director configuration is then obtained by integrating the free-energy density over the volume of the sample, and minimising this, subject to the surface constraints. The geometry of the experiment is shown in Fig. 38.10 and provided the dielectric anisotropy, $\Delta\epsilon$,

Fig. 38.10a,b The geometry for the Fréedericksz experiment used to determine the twist elastic constant, K_2 ; (a) in zero field and (b) above the threshold value

is positive the director will move from being orthogonal to the field to being parallel to it. However, the extent of this twist deformation will vary across the cell, being greatest at the centre and zero at the surfaces, in the limit of strong anchoring. The dependence of the director orientation, at the centre of the slab, with respect to the electric field is shown in Fig. 38.11. As the field strength is increased from zero the director orientation remains unchanged until a threshold value, E_{th} , is reached when the angle between the director and the field starts to decrease continuously. At very high values of the field the director at the centre of the slab tends to be parallel to the field. This behaviour can be understood in the following simple terms. Below the threshold field the elastic energy exceeds the electrical energy and so the director retains its uniform planar alignment. Above the threshold field strength the elastic energy is less than

Fig. 38.11 The dependence of the director orientation θ_m at the centre of a nematic slab on the scaled field strength, $E^* = E/E_{th}$

the electrical energy and so the director begins to move to be parallel to the electric field. The threshold electric field is predicted to be

$$E_{\text{th}} = (\pi/l)\sqrt{K_2/\epsilon_0\Delta\epsilon}, \quad (38.6)$$

where l is the slab thickness. Once the threshold field has been measured and provided the dielectric anisotropy is known, the twist elastic constant would be available. Other Fréedericksz experiments with analogous expressions for the threshold field lead to the determination of the splay and bend elastic constants.

For real display applications (Sect. 38.3) the director alignment at the surface deviates from either uniform planar or homeotropic alignment. This deviation is known as a surface pre-tilt and is illustrated in Fig. 38.6a for near-uniform planar alignment with the tilt direction on the two surfaces differing by 180° . The cell with this arrangement has what is known as antiparallel alignment, so named because of the difference in the tilt direction caused by the direction of rubbing on the surfaces being antiparallel. In zero field, therefore, the director is uniformly aligned across the cell but tilted with respect to the x -axis set in the surface. A continuum theory calculation analogous to the case when the pre-tilt angle, θ_0 , is zero allows the dependence of the director orientation θ_m in the centre of the cell to be determined as a function of the strength of the field applied across the cell. The results of these calculations,

for a nematic with positive $\Delta\epsilon$, are shown in Fig. 38.12b as a function of the scaled field strength, E/E_{th} , where E_{th} is the threshold field for zero pre-tilt. The theoretical dependence for a tilt angle of zero is analogous to that considered for the twist deformation. In other words, below the threshold field the director is parallel to the easy axis and then above this threshold the director moves to become increasingly parallel to the field. When there is a surface pre-tilt the behaviour is quite different and this is especially apparent for a pre-tilt angle of 10° (Fig. 38.12b). In zero field the angle θ_m made by the director with the x -axis is 10° and, as the field increases, so does θ_m . The rate of increase grows as the threshold field is approached and then is reduced as E/E_{th} increases beyond unity. Comparison of this behaviour with the conventional Fréedericksz experiment (Fig. 38.12b) shows that a pre-tilt of 10° has a significant effect on the way in which the director orientation changes with the field strength. Indeed, even for a pre-tilt of just 2° , there is a pronounced difference in behaviour in the vicinity of the threshold field. This clearly has important implications for the accurate determination of the elastic constants [38.20]. It also shows how unique the behaviour is when the surface pre-tilt angle is zero.

Chiral nematics are often employed in liquid-crystal display devices. Locally, their structure is analogous to a nematic but the director is twisted into a helical structure. The continuum theory for the chiral nematic must, therefore, be consistent with the helical ground state structure of the phase. To achieve this, a constant is added to the twist term in the elastic free-energy density. Thus (38.5) for a nematic becomes

$$f = \left[K_1(\nabla \cdot \mathbf{n})^2 + K_2(\mathbf{n} \cdot \nabla \times \mathbf{n} - 2\pi/p)^2 + K_3(\mathbf{n} \times \nabla \times \mathbf{n})^2 \right] / 2 \quad (38.7)$$

for a chiral nematic, where p is the pitch of the helix.

38.2.4 Flexoelectricity

Another property of solids which is mimicked by liquid crystals is piezoelectricity. For solids this is the generation of a macroscopic electrical polarisation as a result of the deformation of certain ionic materials. It is to be expected, therefore, that deformation of the director distribution for a liquid crystal will create a macroscopic polarisation; this proves to be the case [38.24] and the phenomenon is known as flexoelectricity. The origin of flexoelectricity can be understood in the following way. It is generally assumed that mesogenic molecules are

Fig. 38.12 (a) The director alignment in a cell with pre-tilt at the two surfaces assembled so that the rubbing directions are antiparallel. (b) The electric field dependence of the director orientation θ_m at the centre of the cell for values of the pre-tilt angle of 0° (solid line), 2° (dashed line) and 10° (dash-dotted line)

Fig. 38.13a,b The orientational distribution of bent molecules in (a) a uniformly aligned nematic and (b) one subject to a bend deformation; the x -axes are denoted by arrows

cylindrically symmetric but examination of the molecular structure of real mesogens shows that this is not the case. The molecules are asymmetric and at one extreme can be thought of as bent, as shown in Fig. 38.13; here z is the molecular long axis and x is the axis bisecting the bond angle. When the director is uniformly aligned the z -axis will be parallel to the director and the x -axis will be randomly arranged orthogonal to it (Fig. 38.13). If the director is now subject to a bend deformation the molecular long axis will still tend to be parallel to the local director, however, the x -axis will tend to align parallel to a direction in the plane formed by the bent director. This change in the distribution function for the x -axis will introduce polar order into the system and if there is an electrical dipole moment along the x -axis then the deformed nematic will exhibit a macroscopic polarisation, \mathbf{P} . A similar argument shows that, if the molecule is wedge-shaped, a splay deformation of the director distribution will also induce a polarisation in the nematic [38.24].

The magnitude of \mathbf{P} , the induced dipole per unit volume, clearly depends on the extent of the deformation in the director distribution. In the linear response regime the induced polarisation for mesogenic molecules of

arbitrary asymmetry is given by [38.25]

$$\mathbf{P} = e_1 \mathbf{n} \nabla \cdot \mathbf{n} + e_3 \mathbf{n} \times \nabla \times \mathbf{n}, \quad (38.8)$$

where the vectors $\mathbf{n} \nabla \cdot \mathbf{n}$ and $\mathbf{n} \times \nabla \times \mathbf{n}$ represent the splay and bend deformations, respectively. Since the polarisation per unit volume is also a vector then the proportionality constants, e_1 and e_3 , are scalars. These are known as the splay and bend flexoelectric coefficients, respectively, and their dimensions are Cm^{-1} . The determination of individual flexoelectric coefficients is challenging [38.26], however, it seems that $(e_1 + e_3)$ is of the order of 10^{-12} – 10^{-11} Cm^{-1} , although from the previous discussion their magnitude should vary amongst the mesogens because of their dependence on the molecular asymmetry and the size and location of the dipole moment. The molecular model proposed to understand the flexoelectricity of nematics suggests that, for rod-like molecules, devoid of asymmetry, the flexoelectric coefficients should vanish, but that does not seem to be the case. Indeed, it has been proposed that polarisation can result even for rod-like molecules if they possess an electrostatic quadrupole moment [38.27]. This is not inconsistent with the polarisation predicted by (38.8) which follows from the reduced symmetry of a nematic with splay and bend deformations of the director [38.24]. Although the existence of flexoelectricity is of considerable fundamental interest the inverse effect in which the director is deformed from a uniform state by the application of an electric field is of relevance for liquid-crystal displays (Sect. 38.3). This deformation occurs because the polarisation induced by the director deformation can couple with the applied electric field and so stabilise the deformation [38.26]. Since the coupling is linear in the electric field then reversal of the field will simply reverse the deformation; a novel bistable device based solely on this reversal is described in Sect. 38.3.

38.2.5 Viscosity

For a nematogen the fluidity of the nematic phase is comparable to that of the isotropic phase appearing at a higher temperature. It is this fluidity, similar to that of a liquid, which is responsible, in part, for the display applications of nematics. An indication of the fluidity of conventional liquids is provided by a single viscosity coefficient, η , measured from the flow of the liquid subject to an applied stress in a viscometer. The flow behaviour of a nematic is made more complex by its defining long-range orientational order and the resultant anisotropy of the phase.

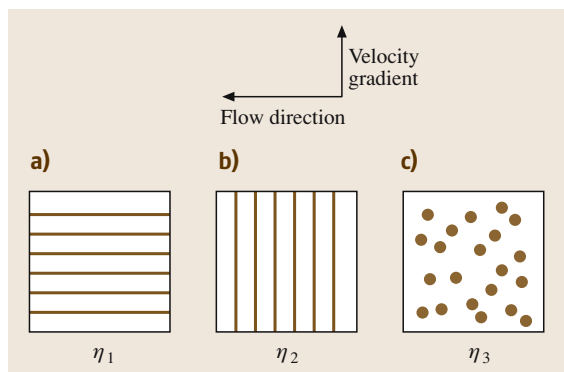

Fig. 38.14a–c The principal flow geometries of the Miesowicz experiments with the director pinned (a) parallel to the flow direction, (b) parallel to the velocity gradient and (c) orthogonal to both the flow direction and velocity gradient

This complexity can be appreciated at a practical level in terms of the Miesowicz experiments to determine the viscosity coefficients of a nematic [38.28]. In these experiments it is helpful to consider flow in a viscometer with a square cross section such that there is a velocity gradient orthogonal to the direction of flow. For a nematic, flow through the viscometer will now depend on the orientation of the director with respect to these two axes. A magnetic field is employed to align the director along a particular axis and it must be sufficiently strong that flow does not perturb the director alignment. There are three relatively simple flow geometries and these are shown in Fig. 38.14: (a) with the director parallel to the flow direction, (b) with the director parallel to the velocity gradient, and (c) with the director orthogonal to both the flow direction and velocity gradient. The viscosity coefficients were denoted by *Miesowicz* as (a) η_1 , (b) η_2 , and (c) η_3 , although other notation has been proposed in which η_1 and η_2 are interchanged [38.29]. The three viscosity coefficients are clearly expected to differ given the anisotropy of the nematic phase and these differences are found to be large. They are illustrated for the room-temperature nematogen 4-methoxybenzylidene-4'-butylaniline (MBBA) [38.30] in Fig. 38.15 where the viscosities are plotted against temperature.

It is immediately apparent that flow is easiest when the director is parallel to the direction of flow, as might have been anticipated. Conversely flow of the nematic is most difficult when the director is orthogonal to the flow direction but parallel to the velocity gradient. The intermediate viscosity, η_3 , occurs when the director is orthogonal to both the flow direction and the velocity

Fig. 38.15 The temperature dependence of the three Miesowicz viscosity coefficients, η_1 , η_2 , and η_3 , for the nematic phase of MBBA; the viscosity coefficient for the isotropic phase is also shown

gradient. Here it is seen that this third viscosity coefficient for the nematic is very similar to the viscosity coefficient for the isotropic phase extrapolated to lower temperatures.

The viscosity coefficient $\eta(\theta, \phi)$ for an arbitrary orientation (θ, ϕ) of the director with respect to the flow direction and velocity gradient can be related to the director orientation. It might be expected that this orientation dependence would involve just the three Miesowicz viscosity coefficients, rather like the transformation of a second-rank tensor from its principal axis system. In fact this is not quite the case and a fourth viscosity coefficient η_{12} needs to be introduced. The orientation dependence is then [38.28]

$$\eta(\theta, \phi) = \eta_1 \cos^2 \theta + \left(\eta_2 + \eta_{12} \cos^2 \theta \right) \times \sin^2 \theta \cos^2 \phi + \eta_3 \sin^2 \theta \sin^2 \phi; \quad (38.9)$$

we see that for the principal orientations $(0, \pi/2)$, $(\pi/2, 0)$ and $(\pi/2, \pi/2)$ the expression gives η_1 , η_2 , and η_3 , as required. The optimum director orientation with which to determine η_{12} is with the director at 45° to both the flow direction and the velocity gradient; the viscosity coefficient for this is

$$\eta(\pi/4, 0) = \eta_{12}/4 + (\eta_1 + \eta_2)/2. \quad (38.10)$$

The value of η_{12} determined for MBBA proves to be significantly smaller than the other three viscosity coefficients.

The four viscosity coefficients have been defined at a practical level in terms of flow in which the director orientation is held fixed. The converse of these experiments, in which the director orientation is changed in the absence of flow, allows the definition of the fifth and final viscosity coefficient. This is known as the rotational viscosity coefficient; it is denoted by the symbol γ_1 and plays a major role in determining the response times of display devices (Sect. 38.4). To appreciate the significance of γ_1 , it is helpful, as for the other four viscosity coefficients, to consider an experiment with which to measure it. In this an electric field is suddenly applied an angle θ to a uniformly aligned director, then providing the dielectric anisotropy is positive the director orientation will be changed and rotates towards the field direction. The electric torque responsible for the alignment is given by

$$\Gamma_{\text{elec}} = -\varepsilon_0 \Delta \varepsilon \sin 2\theta / 2, \quad (38.11)$$

which is the derivative of the electric energy in (38.2). The rotation of the director is opposed by the viscous torque

$$\Gamma_{\text{visc}} = \gamma_1 d\theta / dt, \quad (38.12)$$

which is linear in the rate at which the director orientation changes, with the proportionality constant being γ_1 . Provided the only constraint on the director is the electric field and provided, $\theta_0 \leq 45^\circ$, the director will move as a monodomain so that the elastic terms vanish. The inertial term for a nematic is small and so the

movement of the director is governed by the equation in which the two torques are balanced. That is, the electric torque causing rotation is balanced by the viscous torque opposing it; this gives

$$\gamma_1 d\theta / dt = -\varepsilon_0 \Delta \varepsilon E^2 \sin^2 \theta / 2. \quad (38.13)$$

The solution to this differential equation is

$$\tan \theta = \tan \theta_0 \exp(-t/\tau), \quad (38.14)$$

where θ_0 is the initial orientation of the director with respect to the electric field and τ is the relaxation time

$$\tau = \gamma_1 / \varepsilon_0 \Delta \varepsilon E^2. \quad (38.15)$$

Measurement of the time-dependent director orientation allows τ to be determined and from this γ_1 , given values of $\Delta \varepsilon$. For MBBA the rotational viscosity coefficient is found to be slightly less than η_2 and to parallel its temperature dependence [38.31].

The five independent viscosity coefficients necessary to describe the viscous behaviour of a nematic have been introduced in a pragmatic manner by appealing to experiments employed to measure these coefficients. However, the viscosity coefficients can be introduced in a more formal way as has been shown by Ericksen and then by Leslie in their development of the theory for nematodynamics [38.32]. The Leslie–Ericksen theory in its original form contained six viscosity coefficients, but subsequently Parodi has shown, using the Onsager relations, that there is a further equation linking the viscosity coefficients, thus reducing the number of independent coefficients to five [38.33]. These five coefficients are linearly related to those introduced by reference to specific experiments.

38.3 Liquid-Crystal Devices

The idea to use liquid crystals as electro-optic devices goes back to the early days of liquid-crystal research. In 1918 Björnstål, a Swedish physicist, demonstrated that the intensity of light transmitted by a liquid crystal could be varied by application of an electric field [38.34]. As optical devices of various types became established in the first decades of the 20th century, mainly in the entertainment industry, ways of controlling light intensity became important to the developing technologies. One device that soon found commercial application was the Kerr cell shutter, in which an electric field caused the contained fluid (usually nitrobenzene) to become birefringent. Placing such a cell between crossed polarisers

enabled a beam of light to be switched on and off very rapidly. The first report of liquid crystals being of interest for electro-optic devices was in 1936, when the Marconi Company filed a patent [38.35] which exploited the high birefringence of nematic liquid crystals in an electro-optic shutter. However, it was another 35 years before commercial devices became available which used the electro-optic properties of liquid crystals. The long interruption to the development of liquid-crystal devices can be attributed to the lack of suitable materials. We shall see in this Section how the physical properties of liquid crystals determine the performance of devices.

The optical properties of liquid crystals are exploited in displays, although the operational characteristics of such devices also depend crucially on many other physical properties (Sect. 38.2). Since the devices to be described all depend on the application of an electric field, their operation will be influenced by electrical properties such as dielectric permittivity and electrical conductivity. There is a range of electro-optic effects that can be used in devices, and the precise manner in which the properties of the liquid-crystal materials affect the device behaviour depends on the effect and the configuration of the cell. Thus there is not a single set of ideal properties that can define the best liquid-crystal material, rather the material properties have to be optimised for a particular application. In this section, different devices will be described, and their dependence on different properties will be outlined. The way in which the material properties can be adjusted for any application will be discussed in the final section of this Chapter.

38.3.1 A Model Liquid-Crystal Display: Electrically Controlled Birefringence Mode (ECB)

If an electric field is applied across a film of planar-aligned liquid crystal having a positive dielectric anisotropy, then the director of the liquid crystal will tend to align along the electric field. Thus the director will rotate into the field direction, and the optical retardation or birefringence of the film will change.

Fig. 38.16 Electrically controlled birefringence (ECB) cell

If the film is placed between crossed polarisers, then the change in optical retardation will be observed as a change in the intensity of transmitted light. The configuration for an ECB-mode display is schematically illustrated in Fig. 38.16. This illustrates the principal components of a liquid-crystal display. The liquid crystal is contained between two glass plates that have been coated with a transparent conducting layer, usually an indium–tin oxide alloy. Such treatment allows the application of an electric field across the liquid-crystal film, which can then be viewed along the field direction. For most applications, the surfaces of the electrodes are treated so that a particular director orientation is defined at the surface. This can be achieved in a variety of ways, depending on the desired surface director orientation. For the ECB-mode display under consideration, the director alignment should be parallel to the glass substrates and along a defined direction, which is the same on both surfaces. The standard technique to produce this alignment is to coat the glass plates with a thin (0.5 nm) layer of polyimide, which is mechanically rubbed in a particular direction. The cell is then placed between crossed polarisers, the extinction directions of which make angles of $\pm 45^\circ$ with the surface-defined director orientation.

The unperturbed state of the liquid-crystal film will be determined by the surfaces which contain it. If these have been treated in such a way that the liquid-crystal director is parallel to the surface along a particular direction, then the film will act as an optical retardation plate. Thus incident polarised light will, in general, emerge elliptically polarised, and there will be a phase retardation between components of the light wave parallel to the fast and slow axes of the retardation plate. For electromagnetic waves polarised at $\pm 45^\circ$ to the director the phase retardation ϕ , in radians, will be determined by the intrinsic birefringence of the liquid crystal ($\Delta n = n_e - n_o$), the film thickness ℓ and the wavelength of the light λ :

$$\phi = \frac{2\pi\ell}{\lambda}(n_e - n_o); \quad (38.16)$$

n_e and n_o are respectively the extraordinary (slow) and ordinary (fast) refractive indices of the liquid crystal (assuming that Δn is positive). If the emergent elliptically polarised light passes through a second polariser, crossed with respect to the incident polarisation direction, only a proportion of the incident intensity will be transmitted. The normalised intensity of light transmitted by a pair of crossed polarisers having a birefringent element between them, the axis of which is at $\pm 45^\circ$ to

the extinction directions of the polarisers is given by

$$T = \left(\frac{1}{2}\right) \sin^2 \frac{\phi}{2} \quad (38.17)$$

(the factor of one half appears for incident unpolarised light – if the light is polarised, as from a laser, then the factor is one).

Thus the initial appearance of the cell will be brightest if the cell thickness, birefringence and wavelength are chosen to give ϕ equal to π , 3π , 5π etc. It is normal to select the cell thickness to give $\phi = \pi$, and under these conditions the display is known as *normally white*. It is possible, though less satisfactory, to configure the display so that it operates in a *normally black* state, corresponding to a phase retardation of a multiple of 2π .

Application of an electric field causes the director orientation to change such that the optical retardation of the cell decreases to zero, and hence the cell becomes non-transmitting, at least in the normally white configuration. Under these circumstances the optical retardation across the cell becomes

$$\phi = \frac{2\pi}{\lambda} \int_0^{\ell} \{n_e[\theta(z)] - n_o\} dz, \quad (38.18)$$

where the effective extraordinary refractive index $n_e[\theta(z)]$ depends on the angle $[90^\circ - \theta(z)]$ between the director and the field and is a function of position z in the cell. This effective index is given by

$$\frac{1}{n_e^2[\theta(z)]} = \frac{\sin^2[\theta(z)]}{n_o^2} + \frac{\cos^2[\theta(z)]}{n_e^2}; \quad (38.19)$$

Fig. 38.17 Variation of optical transmission with voltage for an ECB cell between crossed polarisers

when the director is along the field direction $\theta = 90^\circ$, so $n_e(90^\circ) = n_o$, and $\phi = 0$.

The orientational distribution of the director in the cell in the presence of an applied electric field is determined by the strength of the field, the electric permittivity and elastic constants of the liquid crystal, and most importantly by the properties at the interface between the liquid crystal and the aligning surfaces. If the director at the surface satisfies the *strong anchoring* condition i.e. it is unaffected by the applied electric field, and the surface director is strictly perpendicular to the electric field, then the reorientation of the director exhibits a threshold response, known as a Fréedericksz transition. The change in transmitted intensity as a function of voltage can be calculated using continuum theory and simple optics [38.36], and a typical transmission curve for an ECB cell is illustrated schematically in Fig. 38.17.

The threshold voltage for director reorientation is independent of cell thickness, and is given by

$$V_{th} = \pi \sqrt{\frac{K_1}{\epsilon_0 \Delta \epsilon}}, \quad (38.20)$$

where $\Delta \epsilon$ is the anisotropy in the dielectric permittivity and K_1 is the splay elastic constant. However, it is clear from (38.17) and (38.18) that the intensity of light transmitted by the ECB cell depends on the cell thickness and the wavelength of light. This undermines the usefulness of displays based on the ECB mode, since they require cells of uniform thickness and also they will tend to show colouration in white light. Another important operating characteristic of displays is the *angle of view*, i.e. how the image contrast changes as the angle of incidence moves away from 90° with respect to the plane of the cell. This is clear from Fig. 38.16, where the optical paths in the distorted state for observation to the left or right of the perpendicular to the electrodes are clearly different.

In order to construct a useful display from a simple on/off shutter, it is necessary to consider how image data will be transferred to the display. This is known as *addressing*, and to a large extent it is determined by the circuitry that drives the display. However, we shall see that certain properties of liquid crystals also contribute to the effectiveness of different types of addressing. The simplest method of displaying images on a liquid-crystal display is to form an array of separate cells of the type illustrated by the ECB cell, each having a separate connection for the application of an electric field. Images can then be created by switching on, or off,

those cells required to form the image. This technique is known as *direct addressing*, and can be illustrated by the seven-segment displays used in watches and numerical instrument displays (Fig. 38.18).

To create complex displays, a large number of separate cells, known as picture elements or pixels, must be fabricated, usually in the form of a matrix. Providing separate electrical connections for these pixel arrays (e.g. 640×480 for a standard visual graphics array (VGA) computer screen, is impossible, and so other methods of addressing have had to be developed. Historically, the first was the technique known as *passive matrix addressing*, in which the array of cells are identified in rows and columns, and connections are only made to the rows and columns: for an array of $n \times m$ pixels, only $n + m$ connections are made instead of $n \times m$, as required for direct addressing. Each row is activated in turn (sequentially), and appropriate voltage pulses applied to the columns. Only those pixel elements for which the sum of column and row voltages exceeds a *threshold* are switched to an on-state. However, the problem with this method is that many unwanted pixels in the off-state still have a voltage applied, and may be partially activated in the display: so-called *crosstalk*. The time-sharing of activating signals is known as *multiplexing*, and it relies on the addressed pixels holding their signal while other pixels which make up the image are activated. Provided that the multiplexing is on a time scale of milliseconds, any fluctuation in the image goes unnoticed. However, if the multiplexing becomes too slow, the image starts to flicker. In fact there is a limit to the number of rows of the matrix which can

be addressed (n_{\max}), which is related to the ratio of the on-voltage to off-voltage by a result due to *Alt* and *Pleshko* [38.37]:

$$\frac{V_{\text{on}}}{V_{\text{off}}} = \sqrt{\frac{n_{\max}^{1/2} + 1}{n_{\max}^{1/2} - 1}}. \quad (38.21)$$

The cell characteristic which determines the values of V_{on} and V_{off} is the optical transmittance curve, as illustrated in Fig. 38.17. Depending on the desired contrast ratio $I_{\text{on}}/I_{\text{off}}$ for a pixel, then the voltages $V_{\text{on}}/V_{\text{off}}$ are determined. Thus, in the operation of a passively addressed matrix display, there is a tradeoff between the contrast ratio ($I_{\text{on}}/I_{\text{off}}$) and the number of rows i. e. the complexity of the display. The shape of the transmittance curve is determined by the liquid-crystal material properties, and so these affect the resolution of the image displayed. For a desired contrast ratio of 4, the corresponding on/off ratio for an ECB cell might be 1.82. This gives a maximum number of rows as four, which corresponds to a very-low-resolution display, which would be unusable except for a very basic device. This brief description of a simple electro-optic display operating in the ECB mode illustrates that its performance depends on the dielectric, optical and elastic properties of the liquid crystal material used. Additionally, the properties at the liquid-crystal substrate interface and the geometry of the cell will influence the electro-optic response of the cell.

One performance characteristic that is of very great importance is the speed with which the display information can be changed, since this determines the quality and resolution of moving images. The dynamics of fluids are related to their viscosity, and it has already been shown that the viscous properties of liquid crystals are complicated to describe, and are correspondingly difficult to measure. The complication arises because liquid crystals are elastic fluids, and so there is a coupling between the flow of the fluid and the orientation of the director within the fluid. We have seen that the motion of the director can be described in terms of a rotational viscosity, and the optical properties exploited in displays are related to changes in the director orientation. Thus it is the rotational viscosity that is of primary importance in determining the time response of displays. However, the fact that changes of director orientation cause fluid flow in liquid crystals complicates the process.

The time response of a liquid-crystal display pixel can be illustrated by reference to the ECB display, although other cell configurations modify the behaviour to some extent. In what follows, we shall assume that

Fig. 38.18 Schematic of a directly addressed seven-segment liquid-crystal display

the reorientation of the director within a display pixel does not cause the nematic liquid crystal to flow. For a uniform parallel-aligned nematic-liquid-crystal film, the time for the director to respond depends on the magnitude of the electric field (or voltage) applied to the cell. If the voltage applied is only just greater than the threshold voltage, then the time is very long, while if a large voltage is applied, then the director responds quickly. It is found that the time response can usually be represented as an exponential behaviour, although effects of flow will change this. Neglecting these, a response time τ_{on} can be defined in terms of the change in transmitted light intensity as

$$\frac{I(t) - I(0)}{I_{\text{on}} - I(0)} = 1 - \exp \left[- \left(\frac{t}{\tau_{\text{on}}} \right) \right]. \quad (38.22)$$

and the relaxation time for switching on the display is given approximately by [38.38, 39]

$$\tau_{\text{on}} = \frac{\gamma_1 \ell^2}{\pi^2 K_{\text{eff}}} \left[\left(\frac{V_{\text{on}}}{V_{\text{th}}} \right)^2 - 1 \right]^{-1}. \quad (38.23)$$

On removing the applied voltage, the display element returns to its off-state, but with a different relaxation time which is independent of the applied voltage, such that

$$\tau_{\text{off}} = \frac{\gamma_1 \ell^2}{\pi^2 K_{\text{eff}}}; \quad (38.24)$$

here γ_1 is the rotational viscosity coefficient, and the effective elastic constant, K_{eff} that appears in these expressions is the splay elastic constant, K_1 , for the ECB-mode display. These equations can be modified for other display configurations by changing K_{eff} .

Although the ECB-mode display is the simplest that can be envisaged, based on the Fréedericksz effect, there are many disadvantages, in particular with respect to its viewing characteristics, and it has not been used commercially to any significant extent. However, the apparently simple modification of twisting the upper plate by 90° has resulted in the phenomenally successful twisted nematic display, which represents a large part of today's multi-billion-dollar market.

38.3.2 High-Volume Commercial Displays: The Twisted Nematic (TN) and Super-Twisted Nematic (STN) Displays

The simple twisted nematic display is essentially the same as the ECB display depicted in Fig. 38.16, except

Fig. 38.19 Schematic of a twisted nematic display

that the orientations of the surface director of the containing glass plates are rotated by 90° . However, the TN cell, invented by *Schadt* and *Helfrich* in 1970 [38.40], represented a considerable improvement over earlier devices, and rapidly became the preferred configuration for commercial displays. A schematic representation of the TN cell is given in Fig. 38.19.

This twisted configuration for a liquid crystal film was discovered by *Mauguin*, who found that instead of producing elliptically polarised light, such a twisted film could rotate the plane of polarisation by an angle equal to the twist angle between the surface directors of the glass plates [38.41]. In fact by working through the optics of twisted films, *Mauguin* showed that perfect rotation of the plane of polarisation only resulted if the film satisfied the following condition:

$$2\Delta n \ell \gg \lambda. \quad (38.25)$$

Thus for the cell illustrated in Fig. 38.19, the off-state would be perfectly transmitting. This is known as the *normally white* mode. In reality the cells used for TN displays do not meet the *Mauguin* condition, and the transmission for a 90° twisted cell between crossed polarisers and incident unpolarised light is given by [38.42]

$$T = \frac{1}{2} \left(1 - \frac{\sin^2 \left(\frac{\pi}{2} \sqrt{1 + u^2} \right)}{1 + u^2} \right), \quad (38.26)$$

where $u = \frac{2\Delta n \ell}{\lambda}$. Equation (38.26) shows that, for sufficiently large u , the transmission, T is indeed a maximum of 0.5, however it is also a maximum for $u = \sqrt{3}, \sqrt{15}, \sqrt{35}$, etc. These points on the transmission curve correspond to the *Gooch–Tarry minima*; they are labelled as minima, since they were found for a TN cell operating in the *normally black* state. Most commercial cells operate under conditions of the first or second minima so that thin cells can be used, which give faster responses. It is, therefore, important that the birefringence of the liquid-crystal material can be adjusted to match the desired cell thickness, so that the display can have the best optical characteristics in the off-state.

Application of a sufficiently strong electric field across the twisted film of a nematic liquid crystal having a positive dielectric anisotropy causes the director to align along the field direction. Under these circumstances the film no longer rotates the plane of polarised light, and so appears dark. The transmission as a function of voltage for a twisted cell is similar to that shown in Fig. 38.17, except that the transmission varies more strongly with change in voltage above the threshold, and drops to zero much more rapidly. In contrast to the ECB cell discussed above, the threshold voltage for a TN cell depends on all three elastic constants:

$$V_{\text{th}}^{\text{TN}} = \pi \sqrt{\frac{\left(K_1 + \frac{\zeta}{2}(K_3 - 2K_2)\right)}{\varepsilon_0 \Delta \varepsilon}}, \quad (38.27)$$

where ζ is the twist angle (usually $\pi/2$). The relative change of the transmission intensity with voltage of the TN cell is greater than for the ECB cell, and it can be shown that the steepness of the transmission curve increases as the property ratios K_3/K_1 and $\Delta \varepsilon/\varepsilon_{\perp}$ decrease. The on/off voltage ratio for a TN cell is closer to unity, than for an ECB cell, and so for similar contrast ratios more lines can be addressed: up to about 20 for typical cells and materials. This is significantly larger than for the ECB cell, and so the TN cell allows more complex images to be displayed. There is still a wavelength dependence for the transmission, although this is less marked than for the ECB mode. However, even with the improved multiplexing capabilities of the TN display over the ECB cell, it is still not good enough to use for computer screens. One very successful approach to solve this problem was to modify the TN cell geometry so that instead of a 90° twist, the directors on opposite sides of the cell are rotated by about 270° . This is known as a super-twisted nematic cell.

The concept of the 270° super-twisted nematic (STN) display seems at first sight to be irrational

[38.43, 44]. The director is an apolar vector and so there should be no difference between a 270° and a 90° twisted cell. However, it is possible to maintain a director twist greater than 90° if the liquid crystal is chiral. The use of chiral additives in 90° TN cells was already established, since a very small quantity of chiral dopant added to a TN mixture would break the left/right twist degeneracy in the cell and so remove patches of reversed twist, giving a much improved appearance to the display. If the amount of chiral dopant was increased, then the chiral liquid-crystal mixture would develop a significant intrinsic pitch. By adjusting the concentration of the chiral dopant, the pitch of the mixture could be matched to the 270° twist across the cell thickness of ℓ . i. e. $p \approx 4\ell/3$. An STN cell operates in the same way as a TN cell, so that an applied electric field causes the director to rotate towards the field direction, thereby changing the optical retardation through the film and the transmission between external crossed polarisers. However, the additional twist in the STN cell has a significant effect on the optical properties of the nematic film.

The optical characteristics of the STN off-state are usually outside the Mauguin condition, which means that polarised light passing through the cell is not guided, and emerges elliptically polarised. The degree of ellipticity is wavelength dependent, and so in white light the off-state appears coloured, as does the on-state. An ingenious solution to this problem is to have two identical STN cells, one behind the other, but where the second compensating cell has a twist of the opposite sense. In operation, only the first of the cells has a voltage applied to it. The compensation cell acts to subtract the residual birefringence of the liquid crystal layer, and the display now switches between white and black. Despite this additional complexity, the huge advantage of the STN display is the rapid change in optical transmission with increasing voltage, and a full optical analysis shows that under optimum conditions the rate of change of transmission with voltage can become infinite. In modern implementations of the STN display, the residual birefringence can be compensated by an optical film, avoiding the need for double cells. It is easy to operate an STN display with a $V_{\text{on}}/V_{\text{off}}$ ratio of 1.1, which corresponds to an n_{max} of 100. The shapes of the transmission/voltage curve of ECB, TN and STN cells are a direct consequence of the dielectric and elastic properties of the liquid crystal material, but also depend strongly on the configuration of the cells and the surface alignment

In the description given of displays and their performance, some important aspects have been ignored. The

surface orientation of the directors has been assumed to be pinned in the surface plane, which is the requirement for a threshold response. However, it has been found that the performance of displays can be greatly improved if this condition is relaxed, and a pre-tilt is introduced to the cell, such that the surface director may make an angle of up to 60° to the plane of the containing glass plates. This pre-tilt can be introduced by different surface treatments, and it depends on the interfacial properties of the liquid crystal. An important performance characteristic of displays is the angle dependence of the contrast ratio, or more simply how the appearance of the displayed image changes with angle of view. This is largely determined by the display design, and can be accurately calculated from the optical properties of the cell. The refractive indices of the liquid crystal will affect the contrast ratio and angle of view, but precise control of these performance parameters is difficult. Improvements to the appearance in terms of the angle of view or brightness of displays have been achieved by the placing precisely manufactured birefringent polymer films behind or in front of liquid-crystal cells.

38.3.3 Complex LC Displays and Other Cell Configurations

The STN configuration described above used passive matrix addressing, and this opened up the possibility of relatively large-area high-resolution displays, which could be used in laptop computers and other hand-held displays. The next step was to introduce colour by di-

viding each picture element into three sub-pixels with red, green and blue filters. However, the demand in some market sectors for larger displays with improved appearance having higher resolution [extended graphics array (XGA) displays have 1024×768 pixels] overwhelmed the capability of passive matrix addressing, and the alternative method of active matrix addressing is now used for more complex displays. This technique requires each pixel to have its own switch, as in the simple seven-segment display already described. For high-resolution displays hundreds of thousands of switches are provided by thin-film transistors deposited onto the glass substrate, which forms the screen. These are known as thin-film-transistor twisted-nematic (TFT-TN) displays [38.45]. The sophistication of these displays relies on the capabilities of integrated circuit technology, but the properties of the liquid-crystal materials must still be optimised for the device configuration. A representation of a TFT-TN display is given in Fig. 38.20.

Although being described as an active matrix, the TFT-TN display still uses sequential addressing of pixel rows, and so activated pixels must remain switched on while the rest of the display image is created. The TFTs provide a source of voltage to each liquid crystal pixel, which must then hold its charge, as a capacitor, until the image is changed. So another property of liquid crystals becomes important, that of low electrical conductivity, since the charge on a pixel will be lost by conduction through the liquid crystal. This determines the choice of materials for TFT-TN displays. Generally, high dielectric anisotropy is a desirable property for liquid-crystal display mixtures, since it reduces the operating voltage. However, materials with a high dielectric constant tend to have a high electrical conductivity, since charges either from impurities or leached from surfaces will be stabilised in high-dielectric-constant fluids. Thus the selection of suitable materials requires a compromise between its dielectric and conductance properties, and, of course, the all important refractive indices.

Many different cell configurations, which exploit the optical properties of liquid crystals in different ways, have been tried, and some of these have been commercialised to meet particular market requirements. One rather successful approach to the problem of restricted viewing angle has been the development of the in-plane switching mode (IPS) twisted nematic display [38.46, 47]; this is illustrated in Fig. 38.21. The two optical states of the cells are (i) twisted, and (ii) planar (parallel aligned film), and the director is switched between these states by application of an electric field across electrodes on a single plate of the cell. The state

Fig. 38.20 Schematic of a complex colour TFT-TN display

Fig. 38.21 Schematic of an in-plane switching mode display

that is stabilised by the electric field depends on the dielectric anisotropy of the liquid-crystal material. The preferred configuration uses materials having a negative dielectric anisotropy, so that the off-state is a planar-aligned liquid-crystal film. Application of an electric field to the in-plane electrodes will cause the director at the bottom surface to align perpendicularly to its initial direction, and so induce a twist through the cell (Fig. 38.21).

From an optical point of view, the director is always in the plane of the cell, and this means there is less distortion of an image when viewed at angles other than 90° . Another advantage of the IPS device is that the electric field is confined to the lower plate, and the lines of force do not extend across the cell to the grounded upper plate. This means that a very low electrical conductivity of the liquid-crystal material is less important than for conventional TFT-TN displays. The threshold voltage for the IPS-mode device is given by

$$V_{\text{th}}^{\text{IPS}} = \frac{\pi d}{\ell} \sqrt{\frac{K_2}{\varepsilon_0 \Delta \varepsilon}}, \quad (38.28)$$

where ℓ is the thickness of the liquid-crystal film, and d is the separation of the in-plane electrodes. Not surprisingly the threshold depends only on the twist elastic constant, which is usually smaller by about a factor of two than the splay and bend elastic constants. While this helps to reduce the operating voltage, the smaller elastic

Fig. 38.22 Schematic of a twisted vertically aligned display

energy associated with the pure twist deformation results in longer switching times. A further disadvantage of the IPS display is that the optical transmission of the cell is reduced by the requirement to have both electrodes deposited on one plate, thereby making smaller the active area available to display the image.

A configuration which shares some of the characteristics of the IPS cell and has been successfully commercialised is the twisted vertically aligned (TVAN) cell. The two optical states for this configuration are uniform vertical (homeotropic) alignment of the director for the off-state, and a twisted geometry for the on-state (Fig. 38.22). The liquid crystal material used has a negative dielectric anisotropy, so application of an electric field between the plates causes the director to align perpendicularly with respect to the field direction. A small quantity of optically active material (chiral dopant) is added to the liquid-crystal mixture to ensure that the switched director adopts a twisted configuration through the cell. The advantages of this cell are good viewing-angle characteristics and high optical contrast. Improvements in display technology continue to be made, often simplifying earlier devices. For example, high-quality displays described as vertically aligned nematic (VAN) devices are now available based on the TVAN configuration, but without the twist. The material requirement here is for a liquid crystal of negative dielectric anisotropy,

that will align perpendicularly to an applied electric field.

In the devices described above, one state is defined by the surface conditions of the cell, while the other is defined by the action of the applied electric field. A bistable device is one in which two stable field-free states exist, both of which are accessible by switching with an external field. The first bistable liquid-crystal display to be developed was based on a ferroelectric effect observed in chiral tilted smectic C liquid crystals [38.48]. This ferroelectric smectic display has achieved some limited commercial success in specialist markets, but relies on a surface stabilisation of smectic layers, which is very sensitive to mechanical shock. Recently [38.49], bistable nematic displays have been developed in which two alignment states within a liquid-crystal cell, having different optical transmission, can be stabilised. If one of the substrates of a normal cell is replaced by a surface which has potentially two states of minimum energy corresponding to two surface alignments of the director, then it becomes possible to switch these states selectively using an electric field. A suitable bistable surface is provided by a grooved surface (grating) which has been treated with a surfactant to favour homeotropic alignment of the director at its surface [38.50]. Thus the two surface states correspond to (i) that determined by the grating, and (ii) that determined by the surfactant where the director is perpendicular to the substrate. Combining this intrinsically bistable substrate with a second substrate having a director alignment direction perpendicular to the grating direction gives a cell configuration capable of supporting two optically distinct stable states, which can be switched between using an applied voltage. Various director configurations are possible with this type of cell, and one example is illustrated in Fig. 38.23.

In the absence of any perturbation, the director orientation within the cell will be determined by the homeotropic alignment at one substrate and the alignment at the grating substrate. This hybrid (uniform planar and homeotropic) alignment causes a spatially varying director tilt through the sample. Application of an electric field to a positive-dielectric-anisotropy material will cause the director to align parallel to the applied field, and eventually a fully homeotropic configuration for the director is stabilised. The switch back from the homeotropic state to the hybrid state is thought to be due to a flexoelectric interaction. Other alignment configurations are also possible for the so-called zenithal bistable nematic (ZBD) cell. Displays based on these configurations share the good viewing characteristics of both the IPS and TVAN configurations, but they have the great

advantage that the image is retained when the voltage is removed.

All the displays described so far rely on the coupling between an applied electric field and the dielectric properties of the liquid-crystal material, but, as we have shown, other material properties are just as important to the operating characteristics of the display. The appearance of a display depends on the optical properties of the liquid crystal and the cell configuration, but the operating voltage and switching times of a display are crucial in determining the types of application. Changing the nature of the interaction between the switching electric field and the liquid crystal gives rise to another range of possibilities for liquid-crystal devices. Under certain circumstances, a liquid crystal can be made to exhibit permanent ferroelectric (or spontaneous) polarisation, and this couples linearly with an external electric field, in contrast to dielectric properties which couple with the square of the electric field strength. Not surprisingly this makes a big difference to the switching behaviour of liquid crystals.

The final display to be considered is based on flexoelectric coupling between the electric field and the liquid crystal. Flexoelectricity occurs, in principle, with all liquid crystals, chiral or not, and shows itself as a bulk electric polarisation induced by an elastic strain. Conversely application of an electric field can cause an elastic strain. In general, flexoelectricity is rather small and difficult to detect, however it is thought to be responsible for an electro-optic effect observed in chiral nematic liquid crystals, which is being investigated for display applications. The effect, sometimes known as the deformed helix mode [38.51], is similar in some respects to the ferroelectric switching observed in chiral

Fig. 38.23 Schematic of a zenithal bistable device

smectic C phases, but there is no longer a requirement for a layered structure. Chiral nematic liquid crystals spontaneously form helical structures in which the director rotates with a pitch determined by the molecular structure. If an electric field is applied perpendicularly to a chiral nematic helix, then there is a tendency for the helix to unwind, depending on the sign of the dielectric anisotropy. Even if the dielectric anisotropy of the material is zero, there is an elastic strain which can generate a polarisation (flexoelectric polarisation), which will interact with an applied electric field. This may be exploited in a device configuration, where a thin film of a chiral nematic liquid crystal, having a small or zero dielectric anisotropy, is aligned such that its helix axis is parallel to the containing glass plates (Fig. 38.24).

Application of an electric field across the plates will cause a distortion of the helix through the splay and bend flexoelectric coefficients, which appears as a rotation of the optic axis in the plane of the film [38.25]. Reversal of the electric field direction will reverse the rotation of the optic axis, with an intrinsic switching time about one hundred times faster than conventional nematic displays. Optically, the effect observed is very similar to that exhibited by smectic ferroelectric displays.

There are many cell configurations that can be used with liquid crystals to produce optical switches, displays or light modulators, and some of the more important have been described. The precise operation and performance of these liquid-crystal devices depends on both the cell design and the material properties of the liquid crystal. To a large extent the configuration of the liquid crystal within the cell is determined by such factors as the surface treatment of the plates enclosing the liquid crystal and the interactions between the surfaces and the liquid crystal. Our understanding of these interactions is very limited at the present time, and much more research is necessary before a quantitative theory can be formulated. However, given the cell configuration, the performance of the liquid-crystal device depends crit-

Fig. 38.24 Schematic of a deformed helix mode flexoelectric display

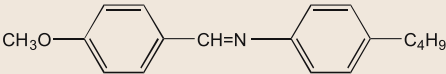

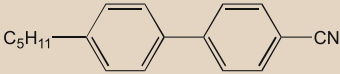

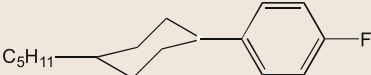

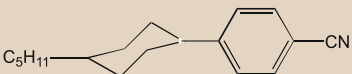

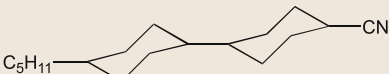

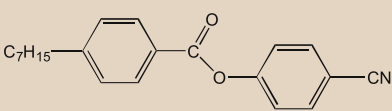

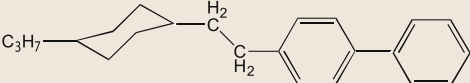

ically on the physical properties of the liquid-crystal material. Thus the electrical switching characteristics will depend on the dielectric properties, while the optical appearance of the device will be determined by the refractive indices. Elastic properties contribute to both the electric field response and the optical appearance, since any deformation of the director will be determined by the elastic properties of the liquid crystal. Finally, the all-important dynamical behaviour will be controlled by the viscous properties of the liquid crystal. All these material properties will be discussed in the next section.

38.4 Materials for Displays

The most important requirement for a liquid-crystal display material is that it should be liquid crystalline over the temperature range of operation of the device. Despite this, some of the first experimental display devices incorporated heaters in order to maintain the material in the liquid-crystal phase: for example, the first liquid-crystal shutter patented by Marconi and

early prototype displays developed by the Radio Corporation America (RCA). It was not until the late 1960s that room-temperature nematic liquid crystals suitable for display applications were discovered. The first of these were based on Schiff's bases, which although easy to prepare, were difficult to purify and were susceptible to chemical decomposition in a de-

Table 38.1 Some typical liquid-crystal materials, including selected physical properties (ex – extrapolated from measurements on a nematic solution)

Compound Transition temperatures (°C) [ref.]	$\Delta\epsilon$ (T °C)	Δn (T °C)	Rotational Viscosity (γ_1 /m Pa s)

vice. One material which attracted particular attention from experimental physicists was MBBA, which has a nematic range of 22–47 °C (Table 38.1). The basic two-ring core linked by an imine group was the structural unit of many compounds having different terminal groups which were prepared for display mixtures in the early 1970s. It was found that mixtures of Schiff's bases often had lower crystal-to-nematic transition temperatures than any of the components, and furthermore would often remain liquid crystalline even below the thermodynamic crystallisation temperature. These two phenomena of eutectic behaviour and

super-cooling have been exploited in the development of materials for devices. The early experiments on liquid-crystal displays were primarily focused on nematic or chiral compounds, but we have seen that other displays have been developed which use different liquid-crystal phases, most importantly the chiral smectic C phase.

Early studies established guiding principles for the development of display materials. First, the phase behaviour must be acceptable, i.e. the right phase stable over a suitable temperature range. Secondly, the material must have the correct electrical and optical proper-

ties for the particular display application envisaged, and above all must be of sufficient chemical purity to prevent any deterioration in performance over time. Again, guided by the early experiments, suitable display materials require the synthesis of compounds of appropriate chemical structure, and then the formulation of mixtures to optimise the properties. There have been a number of reviews of liquid-crystal materials for displays [38.53, 54, 56–59] and these contain many tables of data on a wide range of compounds. In this Section, we will give a brief account of the basic chemical structures used for materials in modern liquid-crystal displays, and then show how mixtures are devised to give the best possible performance characteristics for different displays. It has to be recognised that many of the details of display materials are matters of commercial confidentiality, and so it is not possible to give precise accounts of materials currently used or under investigation. However, the generic chemical structures and principles used in developing suitable mixtures are generally applicable.

38.4.1 Chemical Structure and Liquid-Crystal Phase Behaviour

There is a huge literature on the relationship between the structure of mesogens and the nature and stability of the liquid-crystal phases they form [38.60]. The studies have embraced empirical correlations of chemical structure and phase behaviour, theoretical calculations for simple particles (hard rods, spherocylinders etc.) representing mesogens, and computer simulations of collections of particles of varying complexities. For the display applications considered in this Chapter, the desired phases are nematic, and occasionally chiral nematic or chiral smectic C. Such phases are formed by molecules having extended structures, which usually require the presence of terminal alkyl chains to reduce the crystallisation temperatures. Components in nematic display mixtures typically have two, three or four carbocyclic rings joined directly or through a variety of linking groups.

38.4.2 The Formulation of Liquid-Crystal Display Mixtures

The two requirements for a liquid crystal to be used in a display are a suitable temperature range of phase stability and appropriate physical properties. These requirements cannot be satisfied for complex displays by a single compound, and commercial display materials may contain up to twenty different components. The

formulation of these mixtures is essentially an empirical process, but guided by the results of thermodynamics and experience. The principles behind the preparation of multicomponent mixtures can be illustrated initially by consideration of a binary mixture.

It is well-known that the melting point of a binary mixture of miscible compounds is depressed, sometimes below the melting points of both components. Furthermore, the melting point of the binary mixture may exhibit a minimum at a particular composition, known as the eutectic. This occurs with liquid-crystalline compounds, and provides a method of reducing the lower temperature limit for liquid-crystal phase stability in mixtures. The upper temperature limit of the liquid-crystal range is fixed by the transition to an isotropic liquid. The phase rule of Willard Gibbs predicts that in binary mixtures there will always be a region of two-phase coexistence in the vicinity of a phase transition; that is, the transition from liquid crystal to isotropic occurs over a range of temperatures for which both the isotropic liquid and liquid crystal are stable in the mixture. Because of the weak first-order nature of most liquid crystal to isotropic phase transitions, the two-phase region is small. The character of phase transitions is determined by the corresponding entropy change, and a weak first-order transition has a small ($\approx 2 \text{ J K}^{-1} \text{ mol}^{-1}$) associated entropy. If the latter were zero, then the transition would be second order, and there would no longer be a region of two-phase coexistence. The phase diagrams of multicomponent nematic mixtures can be calculated by thermodynamic methods [38.61, 62] and the transition temperatures of the mixtures can vary with composition in a variety of ways. For mixtures of two liquid-crystalline compounds of similar chemical constitution, the variation of the nematic to isotropic transition temperature is approximately linear with composition [38.63].

It is possible to calculate the variation of the melting point with composition using an equation attributed to Schroder and van Laar. For each component i , the mixture composition (mole fraction x_i) and the melting point of the mixture T are related by

$$\ln x_i = -\frac{\Delta H_i}{R} \left(\frac{1}{T} - \frac{1}{T_i} \right), \quad (38.29)$$

where ΔH_i and T_i are, respectively, the latent heat of fusion and melting point of the pure component i . For a binary mixture there are two such equations which can be solved to give the eutectic temperature and composition. In a multicomponent mixture, the set of

equations (38.29) can be solved subject to the condition,

$$\sum_i x_i = 1 \quad (38.30)$$

to predict the eutectic of the mixture.

While there is a reasonable thermodynamic basis to the prediction of the phase diagrams of mixtures, the determination of the physical properties of mixtures from the properties of individual components is much more difficult. Given the absence of any better theories, it is common to assume that in mixtures, physical properties such as dielectric anisotropy, birefringence and even viscosity vary linearly with the amount of any component, at least for small concentrations. While this may give an indication of the effect of different components on the properties of a display mixture, it can also be very misleading. One theoretical problem is that, for a mixture at a particular temperature, the orientational order parameters of the different components are not equal. The more anisometric components (e.g. three-ring mesogens) are likely to have a larger orientational order parameter than smaller (two-ring) mesogens. Since the various physical properties of interest in displays depend on the order parameter in different ways, it is difficult to predict the contribution of different components to the overall mixture properties. Despite this, many tables of data for liquid-crystal compounds of interest for display mixtures are prepared [38.60] on the basis of extrapolated measurements on mixtures at low composition, normally < 20% w/w. There is always a problem concerning the temperatures at which to compare the physical properties of liquid crystals and their components. Many measurements are made at room temperature, so that this becomes the temperature for comparison. However, a more useful approach is to compare properties at equal reduced temperatures (or at the same shifted temperature, $T_{NI} - T$), since under these conditions the orientational order parameters are likely to be similar.

38.4.3 Relationships Between Physical Properties and Chemical Structures of Mesogens

Electrical and Optical Properties

These properties include the dielectric permittivity, electrical conductivity and refractive indices. The magnitude of the dielectric anisotropy determines the threshold voltage necessary to switch a display, and influences the transmission/voltage characteristics of the cell. Depending on the particular display configuration, a positive or

negative dielectric anisotropy may be required. Refractive indices strongly affect the appearance of a display. Usually the refractive indices or birefringence must be adjusted for a particular cell configuration to give the optimum on/off contrast ratio. Coloration in displays can sometimes occur in materials of high refractive index, and so it is desirable to keep the birefringence as low as possible, compatible with an acceptable contrast ratio. For twisted structures, the magnitude of the birefringence also determines the efficiency of light guiding, and so close control of the values of the principal refractive indices of a display mixture is important. For non-conducting materials, the refractive indices are measures of the dielectric response of a material at very high i.e. optical frequencies, and it is possible to formulate a single theory which relates the dielectric and optical properties of a liquid crystal to its molecular properties. Unfortunately this is not possible for the electrical conductivity. The latter is largely determined by the purity of the liquid crystal, but it is found that the higher the value of the permittivity, the larger the electrical conductivity. Materials of high electrical conductivity tend to leak charge, and so an image may deteriorate during a multiplexing cycle. In general it is desirable to minimise the conductivity of a display mixture, although this was not the case for the first liquid-crystal displays reported [38.64]. These utilised the strong light scattering which results when an electric field is applied to certain nematic materials. The scattering is due to electrohydrodynamic instabilities in liquid-crystal materials which have a significant electrical conductivity. Such materials are not suitable for use in modern, fast-multiplexed displays.

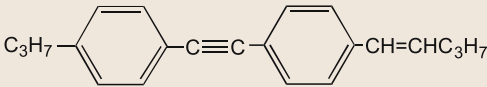

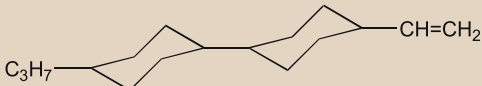

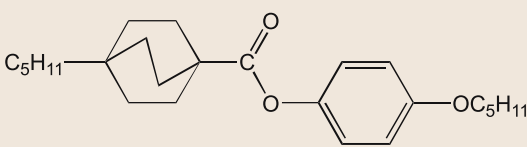

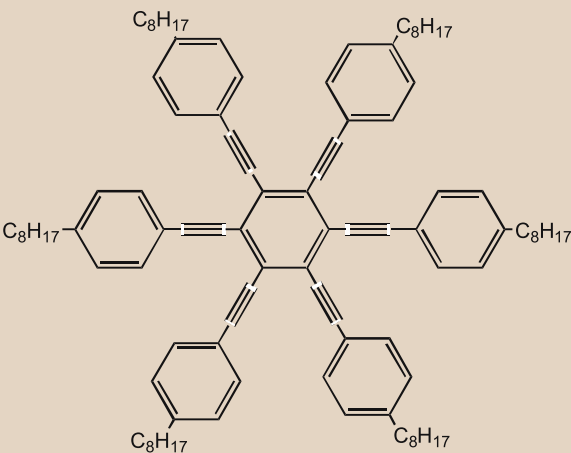

The dielectric anisotropy, $\Delta\epsilon$, and birefringence, Δn , of a nematic can be related to molecular properties of polarisability and dipole moment using a theory originally developed by *Maier* and *Meier* [38.65]. The birefringence is given by

$$\Delta n \approx \frac{NS}{\epsilon_0} (\alpha_\ell - \alpha_t), \quad (38.31)$$

where N is the density in molecules per m^3 and $\Delta\alpha = (\alpha_\ell - \alpha_t)$ is the anisotropy of the molecular polarisability. S is the order parameter, defined in Sect. 38.2.1, and small corrections due to the local field anisotropy have been neglected. Such corrections cannot be ignored in the corresponding expression

$$\Delta\epsilon = \frac{NhFS}{\epsilon_0} \left[\Delta\alpha + \frac{\mu^2}{2k_B T} (3 \cos^2 \beta - 1) \right] \quad (38.32)$$

Table 38.2 Materials of high, low and negative birefringence

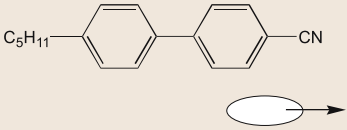

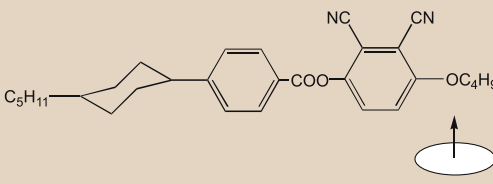

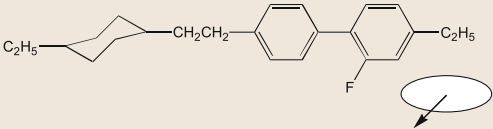

Compound	Transition temperatures	Δn [ref.] ($T^{\circ}\text{C}$)
	T_{NI} 112 °C	0.31 [38.66] (92 °C)
	T_{CrSmB} 23 °C T_{SmBN} 35 °C T_{NI} 49 °C	0.052 [38.59]
	T_{NI} 93.5 °C	0.074 [38.66] (58.5 °C)
	T_{CrN} 80 °C T_{NI} 96 °C	-0.193 [38.66] (61 °C)

for the dielectric anisotropy, especially for materials of high permittivity. In (38.32) h and F are local-field correction factors, while μ is the molecular dipole moment, and β is the angle between the dipole direction and the long axis of the molecule. For molecules containing a number of dipolar groups, μ is the root mean square of the vector sum of all contributing groups. Both the birefringence and the dielectric anisotropy increase with decreasing temperature, and the detailed variation with temperature is largely determined by the temperature dependence of the order parameter S .

The manipulation of birefringence is achieved by changing the chemical constitution of the mesogen. Thus extending the electronic conjugation along the axis of a mesogen will result in an increase in longitudinal polarisability, and hence an increase in birefringence. Saturated carbocyclic rings, such as cyclohexane, and

aliphatic chains generally have small polarisabilities and mesogens containing a predominance of such moieties form low-birefringence liquid crystals. Mixtures for displays require a positive birefringence, which is associated with calamitic or rod-like mesogens. In order to improve the viewing characteristics of displays, optically retarding films are placed in front of the display, and depending on their function, these may be of negative or positive birefringence. The latter can be fabricated by encapsulation or polymerisation of suitable molecules of an extended structure. On the other hand, films of negative birefringence have been made using discotic materials: i. e. mesogenic molecules formed from disc-like structures which have a negative polarisability anisotropy (Sect. 38.1.3). Some examples of liquid crystals having different birefringence are shown in Table 38.2.

Table 38.3 Materials of high, low and negative dielectric anisotropy; the *inset* figure indicates the direction of the total dipole moment with respect to the core of the molecule ($1 \text{ Debye} = 3.335\,64 \times 10^{-30} \text{ Cm}$)

Compound	Transition temperatures	$\Delta\epsilon$ [ref.] ($T^\circ\text{C}$)	Total dipole moment μ (Debye)
	$T_{\text{CIN}} 22.5^\circ\text{C}$ $T_{\text{NI}} 35^\circ\text{C}$	11.5 [38.67] (25°C)	4.8
	$T_{\text{CIN}} 143^\circ\text{C}$ $T_{\text{NI}} 150^\circ\text{C}$	-10.0 [38.68] (145°C)	6.4
	$T_{\text{CIN}} 13^\circ\text{C}$ $T_{\text{NI}} 64^\circ\text{C}$	0.0 [38.69] (58°C)	1.4

The introduction of chirality into liquid crystals has important consequences for their optical properties. The selective reflection of coloured light from the helical structure of a chiral nematic has already been mentioned in Sect. 38.1.2. All chiral materials will rotate the plane of incident polarised light, and the particular optical properties associated with chiral thin films are exploited in many liquid-crystal device applications.

The dipole moment of a molecule is increased if strongly electronegative or electropositive groups are substituted into the structure, with the result that the dielectric permittivity increases. For mesogenic molecules, the locations of the electropositive or electronegative groups are important, since not only the magnitude but also the orientation of the molecular dipole strongly influences the dielectric anisotropy. From (38.32) it can be seen that the dipolar contribution to the dielectric anisotropy may be positive or negative depending on the value of the angle β , since for values of β greater than 54.7° the dipolar contribution to the permittivity anisotropy becomes negative. This is illustrated by the mesogens shown in Table 38.3, where different structures can be designed to give large positive, negative or zero dielectric anisotropy.

The most effective substituent for producing materials of high dielectric anisotropy is the cyano group, and mixtures containing cyano-mesogens were the basis

for the rapid development of complex displays in the 1980s and early 1990s. However, these mixtures tended to have relatively high viscosities, which gave rise to slow switching times. Another disadvantage was the high electrical conductivity associated with the high dielectric anisotropies which caused charge leakage during multiplexing, and hence degradation of the image.

As the demands placed on liquid-crystal materials by more sophisticated display technologies have increased, new families of molecules have been synthesised and screened for their physical properties. However, it is no longer the properties of the pure mesogens that are of interest, rather how they behave in mixtures. For this reason, the physical properties of most components of display mixtures are measured in mixtures, and values for the *pure* mesogens are obtained by extrapolation. Data derived in this way are useful in designing display mixtures and for comparison purposes, but cannot be relied upon to give quantitative information about the relationship between molecular structure and physical properties.

The major display technologies using TN, STN or TFT-TN configurations require display mixtures having a positive dielectric anisotropy. Many materials have been developed to improve the electro-optical behaviour of these displays, particularly using fluorine-substituted mesogens to provide the required dielectric

and optical properties (for examples see [38.54, 58, 70]). However, within the past seven years, new display configurations have emerged, such as the in-plane switching (IPS) and vertically aligned (VAN and TVAN) nematic modes, which require mixtures with negative dielectric anisotropy. Using the design strategy illustrated above for simple mesogens, it has been possible to prepare a large number of materials with the desired negative dielectric anisotropy. These are again mostly based on fluorine-substituted compounds, and as before their properties have mostly been determined by extrapolation of measurements on mixtures.

Elastic Properties

The property known as elasticity is characteristic of liquid crystals, and distinguishes them from isotropic liquids. It has been shown in Sect. 38.2.3 that the macroscopic orientational disorder of the director in liquid crystals can be represented in terms of three normal modes, designated as splay, twist and bend, and associated with each of these deformations is an elastic constant. Since the elastic properties of display materials contribute to the electro-optic response, their optimisation for particular display configurations is important to maximise the performance of commercial devices. However, despite their importance, the relationships between the magnitudes of elastic constants and the chemical structure of mesogens are poorly understood. There is a good reason for this; the optical and dielectric properties are to a first approximation single particle properties. That is they are roughly proportional to the molecular number density and are also linearly dependent on the order parameter. Because elastic properties are a measure of the change in energy due to displacements of the director, they are related to the orientation-dependent intermolecular forces. Thus, at a molecular level, elastic properties are two-particle properties, and are no longer linearly proportional to the number density. A further consequence is that the elastic properties depend to lowest order on the square of the order parameters. Molecular theories of elasticity in nematic liquid crystals have been developed [38.71] and the simplest results suggest that the different elastic constants can be related to molecular shape

$$K_1 = K_2 \propto \langle x^2 \rangle \text{ and } K_3 \propto \langle z^2 \rangle, \quad (38.33)$$

where $\langle z^2 \rangle$ and $\langle x^2 \rangle$ are the average intermolecular distances parallel and perpendicular to the molecular alignment direction, respectively. Thus theory predicts that for rod-like molecules the splay elastic constant

should be smaller than the bend elastic constant, and increasing the molecular length should increase K_3 , while increasing the molecular width should increase K_1 . This is roughly in accord with experimental results, except that the prediction of equal splay and twist elastic constants is not confirmed (Fig. 38.9). In general, the twist elastic constant is about one half of the splay elastic constant. Hard particle theories [38.72] evaluated for spherocylinders provide further guidance on the relationship of elastic constants to molecular shape. These theoretical results can be presented in a simplified way as follows:

$$\begin{aligned} \frac{K_1 - K}{K} &= \Delta(1 - 3\sigma); \quad \frac{K_2 - K}{K} = -\Delta(2 + \sigma); \\ \frac{K_3 - K}{K} &= \Delta(1 + 4\sigma), \end{aligned} \quad (38.34)$$

where $K = \frac{1}{3}(K_1 + K_2 + K_3)$. The quantities Δ and σ are parameters of the theory, where Δ is approximately equal to the square of the length:width ratio of the spherocylinder, and σ depends on the degree of orientational order. Despite the fact that details of internal chemical structure are ignored, these theoretical results for nematics are in approximate agreement with experimental measurements on simple nematics. If the nematic material has an underlying smectic phase, or if there is a tendency for local smectic-like ordering, this can strongly affect the elastic constants. Both the twist and bend elastic constants are infinite in a smectic phase, and in a nematic phase they diverge as the transition to a smectic phase is approached.

The elastic constants contribute directly to the threshold voltage and the response times of displays. Threshold voltages increase with increasing elastic constants, and the elastic constants responsible depend on the configuration of the display. Thus for the planar-aligned electrically controlled birefringence display (ECB), the threshold voltage depends on K_1 , while the switching voltage for TN displays depends on a combination of all three elastic constants (38.27). The IPS display voltage depends only on K_2 , and for VAN and TVAN devices, the threshold voltage is determined by K_3 . Different combinations of elastic constants determine the transmission/voltage curves, which are important in the multiplexing of complex displays. For example, decreasing the ratio K_3/K_1 increases the steepness of the curve for TN displays, and so increases the number of lines that may be addressed. On the other hand, for the STN display, if the ratio K_3/K_1 is decreased, the number of lines that may be addressed also decreases. Identification of the important elastic

constants necessary to optimise the operation of these displays is relatively straightforward; however, manipulation of the components of displays mixtures to give the best results is much more difficult.

Ferroelectric and Flexoelectric Properties

The electro-optic properties considered so far result from interaction of an electric field with the anisotropic permittivity of a material. This might be termed a quadratic response since the dielectric term in the free energy (38.2) is quadratic in the electric field, and as a consequence the electro-optic response does not depend on the sign of the electric field. For materials having a centre of symmetry, such as achiral nematic and smectic liquid crystals, this response is the only one possible. However, if the centro-symmetry of the liquid crystal is broken in some way, then a linear electric polarisation becomes possible, which results in a linear response to an applied electric field. One example of this, in the context of displays, is the chiral smectic C phase, which in the surface-stabilised state exhibits ferroelectricity i.e. a spontaneous electric polarisation. The origin of the symmetry breaking in this case is the chirality of the material, and the polarisation is directed along an axis perpendicular to the tilt plane of the smectic C. Another way in which the symmetry can be broken is through elastic strain. This effect was first described by Meyer [38.24], and it can be represented as a polarisation resulting from a splay or bend deformation (Sect. 38.2.4). Since at a molecular level, strain is related to molecular interactions, the flexoelectric response depends on a coupling of intermolecular forces and the molecular charge distribution. Two molecular mechanisms have been identified which contribute to the strain-induced polarisation. If the molecules have a net dipole moment, then the longitudinal component can couple with the molecular shape to give a splay polarisation along the director axis, while the transverse component couples with the shape to give a bend polarisation perpendicular to the director axis. Even in the absence of a net dipole, a quadrupolar charge distribution in a molecule can result in strain-induced polarisation [38.26]. Both contribute to the splay and bend flexoelectric coefficients, but only the dipolar part persists in the sum $e_1 + e_3$. Thus it is common to quote flexoelectric coefficients as a sum and difference rather than as separate coefficients.

The measurement of flexoelectric coefficients has been a challenge to experimentalists, and there is a wide range of values in the literature for standard materials (Sect. 38.2.4). It is, therefore, premature to

draw any conclusions about structure/property relationships for flexoelectricity from the limited experimental data available. There have been attempts [38.73, 74] to model flexoelectricity for collections of Gay–Berne particles simulating wedge-shaped molecules. Application of the surface interaction model to flexoelectric behaviour [38.75] has allowed the calculation of flexoelectric coefficients for a number of molecules; these calculations include the quadrupolar contribution. The importance of molecular shape is clearly demonstrated, and in particular changes of shape, either through conformational changes or *cis–trans* isomerisation, have large effects on the magnitude and sign of the flexoelectric coefficients.

Flexoelectric effects contribute to the electro-optic response of nematic displays, especially those with hybrid alignment, i.e. planar on one electrode and homeotropic on the other electrode, but they are not usually considered in the optimisation of mixture properties. However, flexoelectric properties are of direct importance to the operation of displays based on the switching of the direction of the optic axis in chiral nematics: the so-called deformed helix mode [38.25].

Viscous Properties

As explained in Sect. 38.2.5, the flow properties of liquid crystals are complicated. Since the materials are anisotropic, the viscosities in different directions are different, furthermore because of the torsional elasticity, viscous stress can couple with the director orientation to produce complex flow patterns. Thus there are five viscosity coefficients necessary for nematics, in addition to the elastic constants, and as many as 20 viscosities for smectic C liquid crystals [38.76]. To relate all or indeed any of these to molecular structure is a formidable challenge. However, for most liquid-crystal displays, the only viscosity of interest is that which relates to the reorientation of the director: the so-called rotational viscosity. This depends on the temperature and order parameter, and on the forces experienced by the rotating director. The rotational viscosities for all liquid-crystalline materials can be represented by one or other of the following parameterised relations

$$\begin{aligned}\gamma_1 &= aS^x \exp\left(\frac{A(T)}{k_B T}\right) \\ \text{or} \\ \gamma_1 &= bS^y \exp\left(\frac{B}{T - T_0}\right),\end{aligned}\quad (38.35)$$

Table 38.4 Fluorinated mesogens of positive and negative dielectric anisotropy used in liquid-crystal mixtures for modern displays. All measurements listed have been obtained by extrapolation from measurements on nematic solutions

Compound Transition temperatures (°C) [ref.]	$\Delta\epsilon$	Δn	Rotational Viscosity (γ_1 /m Pa s)
 T_{CrN} 49 °C T_{NI} (13) °C [38.59]	-6.2	0.1	$\gamma_1 = 110$
 T_{CrN} 80 °C T_{NI} 173 °C [38.59]	-5.9	0.156	$\gamma_1 = 233$
 T_{CrN} 30 °C T_{NI} 58 °C [38.54]	11.3	0.134	$\gamma_1 = 191$ [38.77]
 T_{CrSmB} 43 °C T_{SmBN} 128 °C T_{NI} 147 °C [38.54]	9	0.14	$\gamma_1 = 180$ [38.77]
 T_{CrN} 67 °C T_{NI} 145 °C [38.59]	-2.7	0.095	$\gamma_1 = 218$
 T_{CrN} 88 °C T_{NI} 89 °C [38.59]	-4.3	0.2	$\gamma_1 = 210$
 T_{CrN} 56 °C T_{NI} 117 °C [38.59]	11.1	0.067	$\gamma_1 = 175$

where a , b , A and B are material parameters, and S is the order parameter raised to a power of x or y between 0 and 2. The first of these expressions emphasises the diffusional nature of rotational relaxation in a liquid

crystal, that is molecules rotating in an external potential. The second expression taken from polymer physics describes rotation in terms of free volume, where T_0 is the temperature at which the free volume becomes zero, and the rotational viscosity infinite i. e. a glass transition.

At the simplest level, the rotational viscosity depends on the molecular shape and size. As the length of the molecule increases, from two rings to three rings etc. γ_1 increases, similarly it increases with the length of the alkyl chain. Varying the nature of the rings in the mesogenic core can have a dramatic effect on the rotational viscosity, which correlates well with free volume, as shown in Fig. 38.25, and the glass temperature of the material.

There is a correlation between the increasing dielectric anisotropy and increasing rotational viscosity which can be attributed to local dipolar intermolecular forces which impede end-over-end rotation of molecules. Thus mesogens having cyano-groups in a terminal position tend to have relatively high viscosities. Other dipolar groups such as fluorine do not have such a deleterious effect on viscosity as the cyano-group, and so fluorine-containing mesogens are increasingly preferred in the formulation of display mixtures.

As with the determination of other properties, the rotational viscosities of mesogenic components are often determined by extrapolation from measurements on mixtures doped with the component under investigation. Such a method only provides approximate values to compare different components, but in the formulation of mixtures for display applications it is only the rotational viscosity of the final mixture that is important. Rotational viscosities of some mesogens of interest for display mixtures are given in the tables accompanying this section. In many instances, the viscosities, as with other properties, have been determined by extrapolation from measurements on mixtures. The measurement of rotational viscosities is experimentally difficult, and some authors prefer to quote the results of bulk-viscosity measurements in terms of a kinematic viscosity. In fact there is a good correlation between kinematic viscosity and rotational viscosity, and where

Fig. 38.25 Relationship between the rotational viscosity coefficient γ_1 (Poise = 10^{-1} Pa s) and the geometric free volume (V_{fg}) at 25 °C for bicyclic polar mesogens. Compound numbers represent alkyl series as follows: 1-cyanophenylalkylcyclohexanes; 2-alkylcyanobiphenyls; 3-cyanophenylalkylpyridines; 4-cyanophenylalkylbicyclooctanes; 5-alkoxycyanobiphenyls (After 38.52)

possible both values have been included in the tables. From the various tables, the effect of increasing the molecular length on the viscosity is clearly seen, as is the effect of replacing an F atom with a CN group. Lateral substitution, which produces materials of negative dielectric anisotropy, tends to increase the rotational viscosity. Despite this the fastest nematic displays now use vertical alignment and materials of negative dielectric anisotropy. The operating characteristics of display mixtures depend on the physical properties of individual components in a very complex manner, and optimisation of mixture properties has to be carried out in a concerted way.

Organic Photo

39. Organic Photoconductors

This Chapter surveys organic photoreceptor devices used in electrophotography. Included in the discussion are the materials (polymers, pigments, charge-transport molecules, etc.), device architecture, fabrication methods, and device electrical characteristics that are critical to the successful functioning of an electrophotographic device (printer).

The Chapter is organized as follows. A brief discussion of the history of xerography and the contributions of Chester Carlson is followed by operational considerations and critical materials properties. The latter includes dark conductivity, photodischarge-charge transport, and photogeneration. Organic photoreceptor characterizations of dark decay, photosensitivity, and electrical-only cycling are discussed in detail. This is followed by discussions of photoreceptor architecture, coating technologies, substrate, conductive layer, and coated layers which carry out specific functions such as smoothing, charge blocking, charge transport, backing, and surface protection.

Organic photoconductors, devices fabricated from organic photoconductors, and the applications of these devices, are the topics which will be covered in this chapter. The term *organic* is used in the chemical sense to encompass materials with carbon as a major constituent. This includes molecular as well as polymeric materials that are not naturally occurring but are purposefully designed and synthesized in the laboratory for specific physical, chemical, dark-electrical, and photoelectrical characteristics. Organic photoconductors are single, or more commonly, a formulated blend of materials which have photoconductive characteristics. Put simply, these are materials in which the electrical conductivity increases on exposure to light [39.1, 2]. Organic photoreceptors are thin-film devices made from organic photoconductive materials with physical, chemical, dark-electrical, and photoelectrical characteristics designed for optimum performance in

specific applications. The most important application is in electrophotography, where organic photoreceptors are utilized in machines for digital printing and copying. In this chapter we will discuss details of organic photoreceptor architecture and their composition and characteristics that have enabled their utilization in electrophotographic printing. In this space it will only be possible to touch briefly on many important aspects of organic photoreceptors but references will be provided for those wishing to delve deeper [39.3–6].

Organic photoconductors are materials and organic photoreceptors are devices made from organic photoconductors. The common acronym for an organic photoreceptor is OPC, which of course stands for organic photoconductor, and simply indicates that acronyms are often inscrutable. The application for which organic photoreceptors have received the most attention and development effort is as the photosensitive

image-creating element in electrophotographic-based printers and copiers. In these machines the photoreceptor is a highly uniform, defect-free, multilayer thin film ($\approx 20\text{--}50\text{ }\mu\text{m}$ photoconductor thickness) coated on a metal drum or a flexible belt, with an active area

from 160 to over $12\,000\text{ cm}^2$. Organic photoreceptors for electrophotography were first introduced in the 1960s and, after years of development for improved physical and electrical characteristics, they form the basis of a multi-billion-dollar industry today.

39.1 Chester Carlson and Xerography

Electrophotography has an interesting history [39.7–10] and we will briefly tell this story with emphasis on

the enabling aspects of organic photoreceptors in this technology. The story begins with Chester F. Carlson, a patent lawyer who saw the need for a method of reproducing documents. In his kitchen laboratory in Queens, New York, he demonstrated that a charged photoconductor could be used to produce an electrostatic latent image which could subsequently be visualized by contact with oppositely charged particles. The first electrophotographic image was “10.-22.-38 Astoria”. The patent application was filed on 4th April 1939 and on 6th October 1942, US patent 2 297 691 was issued [39.11]. Figure 39.1 shows the title page of that patent. In concept, electrophotography is a relatively simple process with six (or seven) steps but it took over 20 years to bring it to fruition and another decade to make it truly practical. The essential steps are all illustrated in the US patent cover page: charging, exposure, developing, transfer and fixing. Not pictured are the final steps, blanket exposure and cleaning, to prepare the photoreceptor for the next electrophotographic cycle.

Carlson had great difficulty finding commercial backing for his invention. He was unable to convince the management at a long list of influential and affluent companies that making copies of documents was an attractive business proposition. In the end the Battelle Development Corporation took on the project and made significant advances towards making it more practical. In Carlson’s invention a coating of photoconductive material such as sulfur or anthracene is prepared on a conductive, grounded, metal substrate. The photoconductor is tribocharged by contact with an appropriate material (silk rabbit’s fur, etc.). The photoconductor is then image-wise exposed with light of a wavelength that causes the photoconductive response. The areas struck by light become conductive and the surface charge is neutralized. Thus, there is now a difference in surface charge density, and hence surface potential, between the exposed and unexposed areas. This difference in surface potential, the so-called electrostatic latent image, was visualized by contacting the surface with small marking particles, such as spores from the lycopodium club

Fig. 39.1 Title page of the first U. S. Patent on electrophotography by C. F. Carlson

moss, with surface charge opposite to the original surface charge. The final copy is produced by transferring the *toned* image on the photoreceptor to the receiver (Carlson accomplished this with a heated sheet of waxed paper). Carlson later dubbed his process *xerography*, meaning dry writing, based on the use of dry powder as the marking particles. Electrophotography is a more general term encompassing, for example, the use of liquid toners in which the charged marking particles are suspended in an insulating fluid.

Two significant early advances were the use of amorphous selenium as the photoconductive material and the development of a practical method (the corotron) for the generation of an air corona for surface charging the photoconductive material. The corotron is simply a fine wire held at high potential (above the air ionization threshold of ≈ 7 kV) and shielded on the back with a grounded metal plate. Xerography was eventually purchased by the Haloid Corporation of Rochester, New York, (later to become the Xerox Corporation) with Carlson as a consultant. The first xerographic product was the XeroX Copier model A introduced in 1949. This initial product had totally manual operation which required several minutes to produce a copy. The photoreceptor was a selenium plate that measured 9×14 inches. From these modest beginnings, advances in engineering the various processes and materials progressed in an evolutionary manner leading to the introduction of the automated copy machine, the Xerox 914 in 1959. This utilized a selenium-coated drum photoreceptor. The evolution continues today and new product introductions have rapidly shifted from copiers (reflection of light from a document to expose the photoreceptor) to digital printers (pixel-wise exposure of the photoreceptor based on data from a previously compiled image file) using drum- or flexible-belt-based organic photoreceptors. Early examples of copiers utilizing organic photoreceptors are the IBM copier 1 (1970) and the Kodak Ektaprint 100 (1975). Initially the photoreceptors were *single-layer* in that the photoconductive materials were all contained in a single layer. For high-speed high-quality applications more complex photoreceptors were introduced. These had multilayer structures with each layer being optimized for a specific function. The details of photoreceptor architecture and composition will be discussed later.

There are some subtle differences in the electrophotographic process between copiers and digital printers. Since the electrostatic image in a copier is produced by reflection of the exposing light from a document (black text for example), areas of the document which are dark

(text) reflect no light and the corresponding area of the photoreceptor retains its surface charge. To produce a final print in which the dark areas correspond to dark areas in the original document one must *develop* the image with a marking particle (toner) with charge that is opposite to that on the photoreceptor surface. This process is called *charged area development*. In a digital printer the exposure is controlled by an image file and the image is composed of a microscopic halftone pattern of *pixels*. Pixel size is determined by the desired *resolution* such that 600 dpi corresponds to a pixel size of about $40 \mu\text{m}$. In a digital process it is possible to expose either those areas which will be developed or undeveloped in the final print. The approach sometimes chosen is to expose only those areas which will be toned since most documents are text-based and text occupies only a small fraction of the total document area. This approach decreases the on-time of the exposing system and lengthens its lifetime. Thus, in this case those areas to be developed have been exposed and have decreased surface potential. This process, *discharged area development*, is carried out by using toner with a charge polarity that is the same as that of the photoreceptor surface. Factors in OPC design relating to their optimization for digital imaging have been investigated but in practice the OPCs used in today's copiers and printers differ little [39.12–14]. Discussion of the chemistry, physics, and engineering involved in toners, developers, and development systems is beyond the scope of this chapter [39.15, 16].

In addition to the photoreceptor some of the major subsystems of a modern digital printer are:

- Exposure: scanning laser or light-emitting diode (LED) arrays.
- Development: magnetic brush or other technology with black and/or colored marking particles plus magnetic carrier.
- Transfer: heat, pressure, etc. to remove toner from the photoreceptor and place it on the receiver. In some systems the toner is transferred first to an intermediate drum or web and then to the final receiver.
- Erase: blanket exposure to return the photoreceptor to a uniform surface-charge state.
- Clean: blade or brush to remove untransferred toner from the photoreceptor surface.
- Fixing: melting the toner particles onto the receiver.
- Computers and software: image capture, rendering, and storage, process control, receiver handling, etc.

- Process control: software and hardware (sensors, voltmeters, etc.) to maintain image quality.
- Sensors and controls: for receiver handling.

A full listing would be much longer and the modern electrophotographic printer is a highly complex system where the hardware, software, and materials have been successfully co-optimized to meet the product aims [39.17–19].

Since the photoreceptor surface is either in physical contact with (development, transfer, cleaning), or exposed to, effluents (fusing, corona charging) from the various subsystems its physical and electrical characteristics must be stable to these interactions throughout its life. Much of the development in OPCs has been to extend the photoreceptor process lifetime. Today the most durable OPCs might be replaced after 100 000 or more imaging cycles.

39.2 Operational Considerations and Critical Materials Properties

The steps involved in the electrophotographic process were detailed previously [39.15, 17]. In this section we discuss some of the underlying physics in the formation of the electrostatic latent image. From the point of view of device physics the OPC is a large-area transducer configured as a belt or drum which converts optical information into a latent charge (primary) image. The photoreceptor material is a high-dielectric-strength insulator that is converted to the electrically conducting state with the application of a field and illumination. Phenomenologically, a high field is applied across the thin-film photoconductor (corona charging) and the film is exposed to radiation absorbed by the material. The photon energy is converted into charge carriers at or near the site of absorption and these drift under the influence of the field. Since the charged photoreceptor is an open-circuit device the surface potential decreases as the charges drift through the material and the photoreceptor is discharged.

In this section we focus on some of the key physics and materials issues governing the field-biased motion of electronic charge through the photoreceptor during light-induced xerographic discharge – the process which leads to latent image formation. Work done in optimizing the design and characterization of photoreceptors in order to service an evolving technology operated in a push–pull relationship with the growth in scientific understanding of photoinduced charge generation, injection, transport and trapping first in amorphous semiconductors and then, in what will concern us here, disordered molecular media.

Because the photoreceptor assembly is a sensitized large-area device, the materials which simultaneously optimize all the required properties have always been glassy coatings. (Polycrystalline media are largely unsuitable for a variety of reasons.) The inorganic materials used especially in light-lens copiers were initially amor-

phous chalcogenides [39.20, 21] and to a much lesser extent hydrogenated amorphous Si [39.22, 23]. Much of the early work was therefore focused on the physics and chemistry of amorphous semiconductors. In this case photogeneration and the subsequent transport of charge occur in precisely the same medium, and design latitude is clearly restricted by the particular combination of optical and transport characteristics of that single layer. In addition these inorganic films are relatively brittle and therefore unsuitable for applications which require a belt architecture, i.e., one in which the photoreceptor is required to bend around small rollers. On the other hand, polymer-based OPCs are inherently flexible and multi-layer architectures are readily fabricated such that each layer can be optimized for a particular function such as photogeneration and charge transport [39.24]. In fact, all OPCs for high-end applications have been developed according to this principle with the photoconductor divided into a thin light-absorbing charge-generation layer (CGL) adjacent to the electrode and a thicker charge-transport layer (CTL) which transports holes. With this photoreceptor configuration the surface is negatively charged prior to exposure. The details of OPC architecture and the materials chosen for specific layer functions will be discussed later.

39.2.1 Dark Conductivity

The electrophotographic imaging process begins by applying a surface charge to the photoreceptor. A parallel-plate-capacitor model is appropriate and the surface potential and surface charge density are related through the capacitance per unit area as, $Q/A = (C/A)V = (\epsilon\epsilon_0/L)V$, where Q/A is the surface charge density (C/cm^2), C/A is the capacitance per unit area (F/cm^2), V is the surface potential (V), ϵ is the dielectric constant, ϵ_0 is the permittivity

of free space, and L is the photoreceptor thickness. For a typical organic photoreceptor ($L = 25\text{ }\mu\text{m}$, $\epsilon = 3$, and $V = -500\text{ V}$) C/A is $3.2 \times 10^{-10}\text{ F/cm}^2$, corresponding to 10^{12} charges/ cm^2 . Assuming the surface is composed of molecules with an area of $100\text{ }\text{\AA}^2$ ($10^{-14}\text{ cm}^2/\text{molecule}$) only $\approx 1\%$ of the surface molecules are associated with the surface charge. The applied field (V/L) is $2 \times 10^5\text{ V/cm}$.

Electrophotographic imaging is enabled by a difference in surface potential between exposed and unexposed areas when the imaged area enters the development subsystem. Generally a potential difference of at least 300 V is desired. The materials comprising the bulk of the OPC must be highly insulating. A resistivity of $10^{13}\text{ }\Omega\text{ cm}$ at a field of $2 \times 10^5\text{ V/cm}$ will give rise to a dark decay rate of nearly 200 V/s . Since development typically occurs at a fraction of a second to one second after charging, the photoconductor resistivity needs to be $> 10^{13}\text{ }\Omega\text{ cm}$. Organic polymers such as bisphenol-A polycarbonate meet this requirement and are the major component in OPCs.

There are other sources of dark conductivity such as electrode and/or surface charge injection, bulk charge generation, and/or charge detrapping [39.25]. Electrode injection is prevented with the interposition of a charge-injection blocking layer between the electrode and the photoconductive material. Surface injection is prevented by the chemical composition of the surface layer (which is typically a hole-transporting CTL). Detrapping can be a significant source of dark decay in OPCs and must be controlled by a balance between the process and the materials (the charge-generation material in particular).

39.2.2 Photodischarge–Charge Transport

The photoreceptor must retain charge in the dark and also be photosensitive enough to discharge exposed areas to half their initial charge potential when irradiated with (nominally for a mid-volume laser printer engine) $4\text{--}10\text{ erg/cm}^2$. The xerographic gain or quantum efficiency of supply describes the fractional number of surface charges neutralized per absorbed photon. For a dual-layer OPC it is a complicated convolution of the quantum efficiency of generation in the charge-generation layer, CGL, the efficiency of carrier injection from the CGL to the CTL and the transport parameters of the CTL. For this discussion we will for the moment ignore issues of charge generation and focus on transport. In dual-layer OPCs the majority of photodischarge occurs via charge transport through the CTL with the CGL playing a minor role. In the transport lexicon

[39.24,26] there are essentially two parameters that constitute the figures of merit to characterize charge motion through the polymeric CTL. These are (1) the drift mobility μ , the measure of *how fast* the carrier moves per unit applied field, and (2) the normalized carrier range $\mu\tau$ (τ is the free-carrier lifetime against deep trapping), which is *how far* the injected carrier moves per unit field before becoming immobilized in a deep trap. The time for a photoinjected carrier to traverse the CTL is called the transit time. The transit time t_{tr} , and mobility μ are related to the specimen thickness L according to $t_{\text{tr}} = L/\mu E$. The importance of mobility as a critical parameter in the electrophotographic process can be understood as follows: for an increase in the exposure intensity $d(F)$, the final decrease in surface potential $d(V)$ is proportional to the number of injected carriers and the distance they travel within the CTL. During xerographic discharge, a charge of CV_0 (C is the CTL capacitance and V_0 the initial voltage) traverses the bulk and induces time-dependent variation in the electric field behind the leading edge of the injected carrier front. Thus, as the fastest carriers transit the CTL, the electric field behind them is reduced, and the carriers behind the leading edge transit at a lower field, which in turn makes their velocities lower. Thus during xerographic discharge the transit times of individual photoinjected carriers become dispersed over a wide range, typically about an order of magnitude. For discharge to proceed to completion, even in the complete absence of deep trapping, enough time is required for the slowest carriers in the packet to exit the layer before the photoreceptor reaches the development zone – nominally $0.3\text{--}1.0\text{ s}$ after exposure in mid-volume printers. The latter must be allowed for in practice. Thus, carrier mobility in this particular illustration should exceed $10^{-6}\text{ cm}^2/\text{Vs}$. For example, consider that a dual-layer photoreceptor with a $25\text{-}\mu\text{m}$ CTL, in which there are no deep traps, is subjected to a light flash intense enough to ultimately induce complete discharge (CV_0 of absorbed photons). Consider further that in this CTL the mobility $\mu = 10^{-6}\text{ cm}^2/\text{Vs}$ at $E = 10^4\text{ V/cm}$ and that the device is initially charged to 1000 V . It can be calculated that under these conditions the device will have a residual voltage of 20 V after 0.3 s or 7 V after 1 s . Incomplete discharge, unless compensated for, might result in an inadequate toning potential and a toned density less than desired. Note further that, if the mobility is even lower, the results can become totally unacceptable. For example when the mobility is $\mu = 10^{-7}\text{ cm}^2/\text{Vs}$ under the conditions just described, the residual voltage a full second after exposure is 60 V , even in a completely trap-free CTL. In light of the fore-

going illustration for the trap-free case, which sets the mobility benchmark, the effect of traps in the polymeric CTL must be of paramount concern. More precisely, we are concerned with traps whose release time at ambient temperature discernibly exceeds the period of a complete electrophotographic cycle. In the present context we take the latter as the operational definition of a deep trap. With such traps present it is clearly the case that, after repeated charge-expose cycling, some quantity of image degrading charge would remain immobilized in the bulk for times now exceeding the period of a complete xerographic cycle. If ρ is the density of uniformly trapped space charge in a CTL of thickness L and relative dielectric constant ϵ then there is an associated residual potential V_R , where $V_R = e\rho L^2/2\epsilon\epsilon_0$. Here e is the electronic charge and ϵ_0 is the free-space permittivity. In a nonpolar dielectric medium ($\epsilon = 3$) with a layer thickness of 25 μm , as few as 10^{13} electronic charges trapped per cm^3 already give rise to a residual of 19 V. Unless process control utilizing electronic feedback correction can be employed, bulk-trapping-induced space-charge buildup during cycling can result in severe image degradation. Residual potential arising from bulk-trapped space charge is a critical electrophotographic process parameter. A residual potential can be related to the normalized carrier range, $\mu\tau$, in the weak-trapping limit from the physically plausible ansatz that the residual potential corresponds to that applied voltage for which the carrier range is about half the specimen thickness L . Thus, $\mu\tau$ is approximately $L^2/2V_R$. On this basis the tolerable trap density is defined by the requirement that the $\mu\tau$ product in practical devices should typically exceed $10^{-6} \text{ cm}^2/\text{V}$. Even highly purified polymer will typically contain many chemical impurities in the 1–10 ppm range, which the foregoing calculations show is vastly higher than permissible trap levels. However, chemical impurities, even when present at relatively high concentration, can be rendered trap-inactive by employing molecular design principles to guide the overall choice of active materials. Concepts derived from scientific understanding of photogeneration, injection across interfaces, and electronic transport in disordered organic materials, in combination with the unique compositional flexibility characteristic of the organic solid state, were together responsible for making multilayer OPCs the dominant practical receptor technology for electrophotography.

As discussed above, successful electrophotographic imaging requires that charge transport through the CTL occur with little trapping in the time scale of the electrophotographic cycle. Here we discuss how this

is accomplished in an *impure* organic-chemical-based CTL. The CTL is a glassy solid solution of a charge-transport-active moiety dispersed in a polymer binder. The charge-transport moiety can be molecular or a polymer component. The molecular solutions are called molecularly doped polymers (MDP). The transport-active component is typically 40–50% weight fraction of the CTL. Thus, *doping* in the present context is decidedly different from what doping refers to in conventional semiconductor physics [39.27]. In the latter case the dopant is typically introduced at very low concentration to control the relative proportion of electrons and holes in the bands of a semiconductor crystal leaving optical properties largely unaffected. In a semiconductor crystal at ambient temperature the dominant field driven transport mechanism is scattering perturbed motion of charge carriers in the bands. Under these circumstances, mobility decreases algebraically with increasing temperature, while carrier population in the bands is thermally activated. The convolution of these processes manifests in a thermally activated conductivity. On the other hand, in MDPs under equilibrium conditions the transport-active molecule is in the neutral state, and the glassy films are perfect insulators, that is, there are no free carriers

Fig. 39.2 Log (μ/ρ^2) versus average intersite separation, ρ , of TPD molecules in bisphenol-A polycarbonate ($E = 5 \times 10^4 \text{ V/cm}$). The triangle symbol is the hole drift mobility in pure TPD film

present in thermal equilibrium [39.28]. These systems can nevertheless support relatively efficient charge transport under the action of an applied field when in contact with a charge reservoir. At fixed temperature the drift mobility of extrinsic carriers decreases exponentially with increasing average intersite separation of the active molecule (ρ) so the drift mobility of MDPs can be tuned over a broad range by simply adjusting concentration [39.29, 30]. This feature of tunability can readily accommodate a wide range of xerographic process speeds as described above and is therefore advantageous from a technological point of view [39.31]. This is illustrated in Fig. 39.2 for a common hole-transport material, TPD N,N'-diphenyl-N,N'-bis(3-methylphenyl)-(1,1'-biphenyl)-4,4'-diamine (TPD, Fig. 39.4). The data is in conformity with a simple tunneling model where ρ_0 is the wavefunction localization radius and the transport states are sited on the TPD molecules. At 40–50 wt% doping approximately 10^4 hops are required for the hole to transit a 20- μm photoreceptor.

Drift mobility of holes in CTL films is most conveniently measured by the canonical small-signal time-of-flight (TOF) technique [39.32, 33]. However, for a given composition of the CTL, and all other conditions analogous, the same drift mobilities can be inferred by analyzing transport-limited xerographic discharge in bilayer photoreceptors [39.34, 35]. In TOF, the MDP film is prepared with semitransparent blocking contacts and maintained at a bias which is high enough to insure that the transit time of any excess injected carrier

Fig. 39.3 Temperature dependence of the drift mobility in a film of 50 wt % TPD in bisphenol-A polycarbonate ($E = 2.5 \times 10^5$ V/cm). T_g is the glass transition temperature of the film

is shorter than the bulk dielectric relaxation time. The sample is exposed to a very short and weak pulse of strongly absorbed light (typically 337 nm from a ni-

Fig. 39.4 Chemical structures of representative hole transport materials

trogen laser) incident on the positive electrode. Under these circumstances photoexcited transport molecules are oxidized at the positive electrode to the radical cation (the *hole* in transport terminology). This process sets up a chain of redox steps where electrons are progressively transferred from neutral molecules to their neighboring radical cation. The concentration of the advancing pulse of holes is low, such that the applied field remains uniform during their transit. In the ideal case the current from the advancing pulse of holes is constant until the leading edge reaches the counter-electrode, after which it rapidly decreases. The transit time can be extracted from the transient current and from this the mobility. For a given MDP composition drift mobilities are determined for films of known thickness as a function of applied field and temperature. The drift mobility in MDPs always has a thermally activated temperature dependence; thus the log of the drift mobility scales with inverse temperature, as illustrated in Fig. 39.3, where earlier measurements [39.29] have here [39.36] been extended to encompass the characteristic slope change displayed in the glass-transition region [39.37]. However, in a significant number of cases cited in the

literature [39.4] the analogous scaling is with the square of the inverse temperature, (i.e. non-simple activation), as predicted by the disorder model [39.38]. The experimentally observed scaling with intersite separation, the temperature dependence, and the high degree of disorder in these systems clearly indicate that electronic transport must involve the field-biased hopping of carriers in an energetically inequivalent manifold of states sited on the transport-active molecules. Apart from their technological importance in electrophotography [39.39] and light-emitting displays [39.40], what has made MDPs a laboratory for the study of hopping transport is that a number of key secondary features in their transport behavior are in fact pervasive in other disordered molecular media [39.41]. There is then the suggestion of a common underlying mechanism susceptible to theoretical treatment. Thus, the field- and temperature-dependent behavior of molecular dispersions is also observed in polymers with transport-active pendant groups such as poly(N-vinylcarbazole) [39.42], in polymers in which small molecule moieties are incorporated in a main

Fig. 39.5 Field dependence of the hole drift mobility in the polymer PTPB parametric in temperature

chain [39.43] in sigma-conjugated polymers [39.44, 45] and most recently in certain poly π -conjugated systems [39.46, 47]. Figure 39.5 is a plot of the field dependence of the hole drift mobility in the polymer polytetraphenylbenzidine (PTPB) (see insert for the molecular structure) versus field and parametric in temperature over a 60 K range [39.48]. PTPB is a glassy polymer in which tetraphenylbenzidine (TPD) moieties are covalently bonded into a main chain [39.43]. The data is replotted in Fig. 39.6 to show the explicit dependence of the log mobility on the square root of the applied field. The field dependence is itself temperature dependent and clearly becomes stronger with decreasing temperature. The two TPD-based hole-transport media are closely related but qualitatively identical results are reproduced in polysilylenes and polygermylenes which have a sigma-conjugated backbone capable of supporting electron delocalization as inferred from analysis of absorption and emission spectra [39.49, 50]. For example, hole transport in PTPB can be represented in an Arrhenius plot over the temperature range illustrated in Fig. 39.7. In this purely phenomenological

Fig. 39.7 Arrhenius representation of the temperature dependence of hole drift mobility in PTPB. The field dependence of activation is shown in the *insert*

description the activation decreases with the square root of the applied field, as displayed in the insert. Precisely the same behavior is exhibited when the same phenomenological description is applied to hole drift mobility data in poly(methylphenylsilylene) (PMPS), as shown in Fig. 39.8. Combining drift mobility [39.51] and spectroscopic data [39.52] has in fact suggested that transport in these sigma-conjugated polymers involves the hopping of holes among chromophore-like main-chain segments of varying length whose function for transport is therefore analogous to the TPD sites in PTPB. More recently the convoluted pattern of behavior first identified in MDPs and therefore clearly characteristic of hopping among discrete energetically inequivalent molecular sites has been reported in TOF experiments on π -conjugated systems notably the phenylene vinylenes. The sites, like those in polysilylenes, are interpreted to be domain-like backbone segments of varying conjugation length [39.46, 47]. These combined results and the recurrent pattern of behavior they reveal in systems

Fig. 39.8 Arrhenius representation of the temperature dependence of hole drift mobility in poly(methylphenylsilylene), PMPS. The field dependence of activation is shown in the insert. T_g is the glass transition temperature of the PMPS film

of widely varying composition and morphology suggest that a transport theory must be founded on universally shared characteristics [39.53]. The theoretical literature stimulated by these observations is in fact extensive and far too detailed to be adequately described here. In the present context it suffices to comment briefly on certain general trends. The activated temperature dependence universal to all these materials systems arises because states in the hopping manifold are energetically inequivalent. Energetic inequivalence can be understood on the basis of site relaxation accompanying polaron formation [39.54–56]. Energetic inequivalence of sites is also a common feature of disordered solids resulting from site-to-site fluctuation of the static and dynamic electrostatic potential [39.38, 57, 58]. The combination of both effects cannot be excluded. In fact, there is a general need to develop the framework to distinguish the relative contributions of these key processes in the analysis of experimental data [39.59, 60]. A particularly challenging issue has been the attempt to account for the special features of the Poole–Frenkel-like field dependence illustrated in Fig. 39.6. Polaron models typically predict that the log mobility should scale linearly with the applied field [39.54, 61]. The disorder model based on analysis of Monte Carlo computer simulation of hopping on a finite lattice as originally proposed by Bässler [39.38] was in fact able to self-consistently account for a number of key experimental features in terms of a limited set of disorder parameters. On the other hand, it could only model the observed field dependence over a very narrow range. It was later recognized in the formulation of dipole disorder models [39.62, 63], that slow site-to-site variation, as distinct from fully random fluctuation, in the effective electrostatic potential could more properly account for the field-dependent behavior of mobility commonly observed over several orders of magnitude [39.64–66]. The more general formulation of the disorder model developed by Dunlap and coworkers, treats the disorder potential as fully correlated and therefore slowly varying, and argues that such a supposition is physically plausible on general grounds in glassy solids.

If every chemical impurity remaining in even the most scrupulously processed polymer film could act as a trap, organics as a materials class would be completely excluded as a basis for the design of xerographic photoreceptors. Trap-free transport in CTLs was achieved not by entirely eliminating impurities but by properly designing the transport-active moiety [39.67, 68]. The associated studies first carried out in this technologically critical context on molecularly doped systems [39.69] were instrumental in generally

elucidating trap interactions in hopping systems and in first unambiguously illustrating and analyzing the mechanism of trap-controlled hopping transport [39.70]. It was already pointed out that hole transport is supported in MDPs when the neutral transport molecule is donor-like. For electrons the corresponding neutral transport molecule is acceptor-like in character. In each case, the CTLs are typically unipolar when analyzed by TOF or xerographic techniques. As it turns out the principle (simple in hindsight) which applies for example to hole-transport CTLs is to make the transport molecule significantly more donor-like than any of the resident impurity species. The limit is that the material must be stable to air oxidation. From an energetic point of view the impurity levels which then lie above the hole transport states are anti-traps. An important class of small molecules which have these desired characteristics are the aromatic amines and TPD is a prime example of a particularly strong donor in this class of molecules. The trap-free nature of these transport layers is xerographically apparent because there is no buildup of bulk space charge as measured by Kelvin-probe techniques [39.71] even after tens of thousands of CVs of holes are discharged through a photoreceptor with this CTL as a component. The trap-free nature of hole transport can also be independently demonstrated by combining TOF drift mobility and analysis of current–voltage measurements carried out on any transport layer fitted with a semitransparent blocking contact on one surface and an ohmic contact on the opposite face [39.72–74]. Figure 39.9 illustrates the result for the polymer PTPB in which TPD is covalently incorporated as the transport active unit [39.73]. Semitransparent Al on the films exposed surface is used for the TOF measurements of drift mobility. Dark injection occurs under positive bias from the gold-coated mica substrate onto which the PTPB film had initially been deposited. PTPB is highly insulating so that the bulk dielectric relaxation time is always much longer than the transit time of any excess injected carrier at all applied voltages. With the Al contact under positive bias, hole drift mobility is measured as a function of applied voltage V . From the measured drift mobility the trap-free space-charge-limited current density (TFSCLC), J , [39.75] that would be sustained by an ohmic contact under positive bias can be calculated to a good approximation, even when the drift mobility is itself field dependent [39.76, 77] using the expression $J = 9\epsilon\epsilon_0\mu V^2/8L^3$. These values are represented by open circles in Fig. 39.9. The electric field in the film is, of course, nonuniform and E in plots of this sort is simply a shorthand for V/L ,

Fig. 39.9 The field dependence of the dark current for a PTPB film at 323 K measured with positive bias applied to an Au coated Mica substrate (*filled circles*). The trap free space charge limited current (*open circles*) is calculated from the hole drift mobilities obtained by the time of flight method

where V is the externally applied voltage. It should be noted that, under the present conditions, the TFS-CLC is in principle the maximum current that the bulk of a transport medium such as PTPB can demand from a contact in the steady state. It should also be noted that the observation that an injecting contact under test is capable of sustaining a space-charge-limited dark current is a *prima facie* demonstration of ohmicity [39.24]. Filled circles represent the steady-state current measured when positive bias is applied to the substrate. That these calculated and measured currents coincide demonstrates that the injecting Au contact is ohmic and that the PTPB film is trap-free. Similar results have been obtained for other commonly used CTL MDPs such as TPD in bisphenol-A polycarbonate and in films of poly(methylphenylsilylene).

39.2.3 Photogeneration

The CGL material is designed to strongly absorb light from the exposure system (red to near-infrared LEDs

and lasers are typical). In a typical dual-layer OPC the CGL material is a thin (submicron) coating of a dispersed pigment. Simply, the pigment material absorbs a photon and mobile charge is created which is *injected* into the CTL and then drifts under the influence of the applied field to discharge the device. Charge generation is a very complex topic [39.78]. In general terms, absorption of a photon produces an excited state (exciton) of a correlated hole–electron pair (valence band and conduction band, respectively) which has some mobility. Measured exciton ranges can be on the order of 0.1 μm . The exciton may then undergo recombination, with the release of energy to the environment, or it may be converted into charges. Conversion into charges can occur *spontaneously* or through chemical (impurities or dopants) or physical (crystal defects or the crystal surface) interactions. With the trapping of one of the charge carriers the other is free to drift under the influence of the applied field and geminate recombination is suppressed. The mobile carrier (assume holes) must drift to where it is in contact with the hole transport moieties of the CTL. In fact, in most cases the CTL penetrates and mixes with the CGL so that, even if the CGL is formulated without transport material, we can assume that these molecules are in molecular contact with the pigment particle surface. Now the *hole* is available to oxidize or *inject* into the transport moiety to produce the radical cation. Useful hole-transport materials have relatively low oxidation potentials [≈ 1 V versus the saturated calomel electrode (SCE)]. The oxidation potential must be lower than that of the hole at the pigment surface but not so low that the material is unstable to air oxidation. The CTL hole is now transported through the CTL, discharging the photoreceptor, by sequential one-electron redox reactions between adjacent transport molecules as described in the previous section.

The charge-generation mechanism is characterized as *intrinsic* when the hole is generated within the pigment particle without the influence of any externally added materials. In this case the hole is injected into the CTL with concomitant oxidation of a transport moiety at the pigment surface. *Sensitized* generation is said to take place when the photoconductivity is enhanced by an added material (dopant). In this case the dopant is available to react with the pigment exciton at the particle surface. In most cases the dopant is in fact the hole-transport moiety. Dopants may also influence charge generation by forming a (charge-transfer or other) complex which facilitates charge separation. Such complexes may be accessed by direct photoexcitation

Fig. 39.10 Chemical structures of representative electron transport materials

or via exciton diffusion. Sensitization of the photoconductivity of poly(*N*-vinyl carbazole) (**PVK**) by electron acceptors such as **TNF** (Fig. 39.10) has been extensively studied [39.79–87]. Charge-generation mechanisms in pigment-based CGLs depend on the pigment molecular structure, crystal structure, morphology, and on the transport molecule used in the formulation.

The fundamental quantity of interest in charge generation is the quantum efficiency as a function of field. A strong field dependence is always observed, as shown in the example of Fig. 39.11. Several models have been proposed to explain charge-generation characteristics. These will be summarized here but more complete discussions can be found in *Pope and Swenberg* [39.78], *Popovic* [39.89], *Law* [39.3]; *Borsenberger and Weiss* [39.4], and *Weiss et al.* [39.6]. One of the early models to be applied to organic photoconductors was the Onsager model of geminate recombination [39.90]. The 1938 theory gives the probability that a charge pair in thermal equilibrium will separate under the influence of an applied field in competition with geminate recombination. In this model charge separation occurs from an upper vibrational state to produce a *geminate* pair of charges which either recombine due to their Coulombic attraction or are separated under the influence of the applied field. The parameters in this model are the field-dependent quantum efficiency for geminate-pair formation, η_0 , and the initial separation distance of the geminate pair (r_0) [39.91]. The data in Fig. 39.11

Fig. 39.11 Quantum efficiency of the field dependence of generation for a dual layer dye-polymer aggregate based OPC. The solid lines were calculated from the Onsager model with $\eta_0 = 0.60$ and r_0 as shown. After [39.88]

is for a dual-layer dye-polymer-aggregate-based OPC with varying concentrations of charge-transport material (tri-*p*-tolylamine, TTA) in the CTL [39.88]. The data has been fit to the 1938 model with $\eta_0 = 0.60$ and r_0 as shown. The model has been refined using a modified basis, also due to *Onsager* [39.92]. Further refinements have involved modifications of the distribution function assumed for the separation distances [39.93, 94]. This model has been successfully used to describe charge generation in amorphous materials [39.95]. However, these models predict a wavelength-dependent quantum efficiency and a photoconduction threshold which is at higher energy than the absorption, neither of which is observed in pigment-based generation materials. A model for charge generation in these materials invokes decay (radiative or radiationless) of the initially formed excited state followed by a competition between field-dependent charge separation and internal conversion [39.96]. Sensitized generation occurs with the reaction of the thermalized excited state with a dopant. Studies of the field dependence of pigment

fluorescence quenching and lifetime have been used to sort out the details with specific generation materials [39.89,97–99].

The quantum efficiency for carrier generation can be defined in several ways, as described above. The efficiency of geminate-pair formation refers to the initially produced charge pair and this is also the efficiency which has been obtained with fluorescence quenching studies. On the other hand, the generation efficiency determined with xerographic discharge al-

ways includes some contribution from charge transport because a measured decrease in photoreceptor surface potential is due to charge motion. In addition, very-high-intensity exposures may give rise to (bimolecular) recombination of positive and negative carriers during transport [39.100–104]. Quantum-efficiency determinations from xerographic discharge are carried out with very short, low-light-intensity continuous exposures to minimize the influence of charge transport and recombination (see the following section).

39.3 OPC Characterization

Photoreceptors may be characterized by many techniques. On the one hand one wishes to determine the fundamental characteristics of the materials, while on the other hand one wishes to determine electrophotographic performance-based characteristics of the photoreceptor. The quantum efficiency of charge generation and, depending on the model chosen, the initial separation distance of the charge pair, are common characterizations. Electrophotographic performance characterizations include dark decay, photoinduced discharge sensitivity, and residual potential as well as their stability to electrical-only cycling.

39.3.1 Dark Decay

The quantity of interest is the rate of dark discharge (V/s) as a function of field and environment. However, the dark decay characteristics of a dark-adapted photoreceptor when incrementally corona charged to higher and higher fields will be significantly different from what is observed in the electrophotographic process. This is because OPCs seldom behave as perfect capacitors and there is typically a depletion charging component where previously trapped charges are mobilized and drift in the photoreceptor on the application of the corona charge [39.105]. Thus, in addition to field and environment, the observed dark decay characteristics depend on prior exposure history (trapped charges), corona charger characteristics, and timing. Thus, a given photoreceptor will have a higher dark decay rate if the photoreceptor is charged exactly to the desired initial potential (V_0) and the dark decay rate determined immediately, as opposed to charging well above the desired potential and measuring when the surface potential decreases to the desired potential. Dark decay measurements which are meaning-

ful to the electrophotographic process must be carried out in an apparatus in which the exposures, charging, and timing elements are fixed. Dark decay is an important characteristic of an OPC because, although process control will attempt to maintain V_0 , the imaging system in a printer will in general not tolerate a significant V_0 drop.

39.3.2 Photosensitivity

Measurements to determine fundamental characteristics (quantum efficiency of generation materials, mobility, etc.) are often carried on photoreceptors that differ from what might be eventually used in a printer. The layer of interest (CGL or CTL) may be isolated or the device may be modified with the application of a vacuum-deposited electrode (Au is common) on the free surface. Common fundamental characterizations include quantum efficiency as a function of field and wavelength, and mobility. Mobility was discussed in Sect. 39.2.2. The quantum efficiency of carrier generation has several definitions as applied to OPCs. On the one hand it can refer to the number of ion pairs generated per incident or absorbed photon. This fundamental characteristic might be determined experimentally by fluorescence quenching, or calculated based on a model such as the Onsager model discussed above. On the other hand a photodischarge efficiency can be determined based on the decrease in surface potential per photon absorbed or incident. The photoinduced discharge (PIDC) method is commonly used to characterize OPCs as a function of field, wavelength, temperature, humidity, exposure intensity, etc. The photoreceptor is corona charged to apply the desired field and is photodischarged. Using the parallel-plate-capacitor model, $Q = CV$ (terms as defined previously), the change in surface charge den-

sity can be calculated from the decrease in the surface potential. The change in surface charge density per unit area per photon incident or absorbed is a measure of photosensitivity. This measure includes the efficiency of charge generation, injection into the CTL, and transport through the CTL. Because of carrier bimolecular recombination and range limitations the quantum efficiency determined using this method may depend on the light intensity and the extent of photodischarge. The photodischarge method is carried out with either continuous or flash exposures. With continuous exposures ($\text{J}/\text{cm}^2/\text{s}$) the surface potential is monitored as a function of time. One measure of OPC photosensitivity which relates to the electrophotographic process is the exposure required to discharge the photoreceptor a fixed amount, often 50%, from an initial potential. This is typically carried out using exposures (wavelength and duration) relevant to a particular electrophotographic process. The photoreceptor sensitivity is usually reported in terms of J/cm^2 (the inverse is often used to report spectral sensitivity). A related method is to determine the initial photodischarge rate (dV/dt). This can be related to the decrease in surface charge density through the capacitance, $dQ/dt = C dV/dt$. The light intensity is kept low and the discharge time short to avoid space-charge perturbations during charge transport and to keep the field essentially constant. The ratio of the decrease in surface charge density to the exposure ($\text{photons}/\text{cm}^2$) is a measure of photodischarge efficiency. In fact the photodischarge per exposure ($\text{V}/\text{J}/\text{cm}^2$) is another commonly used metric for OPC photosensitivity. When determined as a function of field, data obtained in this manner can be analyzed in terms of the Onsager models. Because photosensitivity depends on field (surface potential per unit OPC thickness) and the exposure produced decrease in surface charge density (related to the change in surface potential through $\Delta Q = C \Delta V$), meaningful comparisons can only be made between OPCs of similar thickness, charged to similar initial potentials, and exposed to similar discharged potentials.

For a process using a flash exposure the photoreceptor discharge is determined at several exposure levels (with the surface potential determined at a fixed time after the exposure) and the data is plotted as surface potential (V) versus $\log(\text{exposure}, \text{J}/\text{cm}^2)$. An arbitrary photodischarge point (typically 50%) can be determined

from this plot for comparison purposes. The utility of this characterization is that the exposure characteristics and the timing for reading the discharged surface potential directly relate to the printing process. As discussed above, short high-intensity exposures may give rise to Langevin recombination [39.102, 104, 106], resulting in decreased sensitivity (reciprocity failure) relative to low-intensity exposures.

An often overlooked sensitivity factor is that there are more photons per energy unit (J) as the wavelength increases. For example, there are about 30% more photons/ J at 820 nm relative to 630 nm. Thus, for a photoreceptor with a given quantum efficiency for carrier generation the sensitivity will increase with increasing wavelength of the exposure source.

39.3.3 Electrical-Only Cycling

Electrophotographic performance characterizations are necessarily carried out on the photoreceptor in an apparatus which has the key elements of the electrophotographic process. The most *relevant* apparatus would of course be the fully configured printer. However, the use of such a complex device is often undesirable, or unnecessarily, for screening purposes. In the laboratory it is common to use *electrical-only* test fixtures in which the process always includes charge and expose, and may include erase (or unique process elements), with the surface potential being determined after the application of each. With an apparatus such as this it is possible to determine process-relevant characteristics such as: chargeability, dark decay, photosensitivity, and residual potential, all as a function of cycling. Of course large changes in any of these characteristics is generally undesirable and long cycling (10–100 kcycles) is often necessary to adequately determine the electrical stability of the photoreceptor to the electrophotographic process. Such stability is a necessary, but not sufficient, condition for eventual commercialization, and extensive testing in the machine for which the photoreceptor was designed is always the final step in the development process. Other factors, often connected to the device physical characteristics (wear rate, corona chemical sensitivity, layer adhesion, seam strength, etc.) may in fact determine the eventual success or failure of a particular OPC in a printer.

39.4 OPC Architecture and Composition

As we have described, OPCs are large-area thin-film devices that are insulating in the dark and become conductive when exposed to light. A high field is applied by exposure to an air corona (or similar charging method) and the photoreceptor is image-wise exposed to produce an electrostatic latent image. The surface potential in the exposed areas is determined by the exposure intensity and the OPC photosensitivity while the surface potential in the unexposed areas is determined by the dark conductivity. The development system deposits charged marking particles (toner) on the photoreceptor surface according to the difference in surface potential between the exposed and unexposed areas. The key photoelectrical processes which enable latent image formation are photoinduced charge generation and the transport of the generated charge through the device. Organic photoreceptors accomplish this in a multilayer architecture with specific materials (monomers and polymers) designed and optimized for specialized functions: binder, charge generation, charge transport, dark conductivity, etc. In this section we will discuss the architecture and composition of organic photoreceptors with details on the function and composition of each layer.

39.4.1 OPC Architecture

The choice of photoreceptor thickness is a balance between capacitance, surface potential, and internal field. Capacitance relates to surface charge density, which determines the achievable developed toner density for toners with a given surface charge per area. Surface potential, in combination with the development system, provides the potential difference to attract toner to the photoreceptor surface. The internal field enables efficient charge generation and transport. In most electrophotographic printing machines the balance is achieved with an OPC thickness of $\approx 20\text{--}30\text{ }\mu\text{m}$ and a surface potential of 500–1000 V.

A schematic cross section of a fully configured modern electrophotographic photoreceptor is shown in Fig. 39.12. In its most simple form the photoreceptor consists of a conductive substrate and a single layer of photoconductive material to accomplish charge generation and transport. The advantage of this structure is in its simplicity, but the disadvantage is that not all characteristics will be optimum. In the modern embodiment the photoreceptor is constructed with separate layers for charge generation (CGL) and charge transport (CTL). Other layers shown in Fig. 39.12 include: sub-

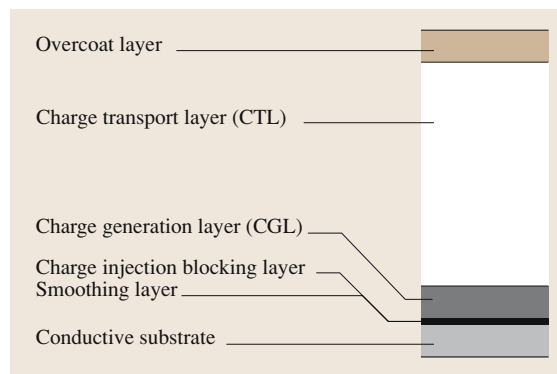

Fig. 39.12 A schematic cross section of a fully configured “modern” electrophotographic photoreceptor

strate, smoothing layer, charge-injection blocking layer, charge-generation layer (CGL), charge-transport layer (CTL), and protective overcoat layer. Additional layers, such as adhesive interlayers, and a back-side anti-curl layer may also be present. OPCs with separate CGL and CTL are termed dual-layer. Each of these layers may be a complex formulation of materials. The advantage in separating layers is that each layer can be optimized for its specialized function. This adds materials expense and manufacturing complexity but has the advantage of superior performance.

In a single-layer photoreceptor when exposed with strongly absorbed radiation directed at the free surface, charge generation will occur near the free surface and the photodischarge will be dominated by the transport of positive or negative charge through the bulk of the layer. The polarity of the mobile charge will be the same as the applied surface potential. In most commercial dual-layer photoreceptors the architecture is substrate–CGL–CTL. Because the CTL is formulated for hole transport, dual-layer OPCs are charged with a negative surface potential. Positive corona charging has some advantages over negative (better uniformity and less ozone production). A single-layer OPC can function with either a positive or negative surface charge depending on the exposure direction and the transport characteristics of the materials used in the formulation. Positive-charging dual-layer photoreceptors with the architecture substrate–CTL–CGL have been commercialized but these require a protective overcoat to prevent the CGL from being damaged by contact with the electrophotographic process elements. The typical substrate–CGL–CTL architecture will function with

positive charging if the CTL is formulated for electron transport. Electron-transporting CTLs have been widely studied by not yet commercialized.

In a multilayer photoreceptor the principle is that the functions of each layer are optimized. Thus, with separate CGL and CTL the former is designed for strong absorption of the wavelength of light used in the process and efficient charge generation, and the latter is optimized for the injection of photogenerated charge from the CGL and transport of that charge to the free surface. In general, most charge-generation materials efficiently transport only one polarity of charge (electrons or holes depending on the material) so that it is generally desirable to have the CGL as thin as possible while retaining the required optical density at the exposure wavelength. It is also necessary that the CGL be uniform over the entire area of the photoreceptor to maintain consistent sensitivity for the entire photoreceptor surface. Submicron CGLs are typical of the photoreceptors used in most modern digital printers. The CTL determines the device capacitance and a thickness of $\approx 25\text{ }\mu\text{m}$ is typical. However, the CTL thickness also influences the ultimate latent-image resolution in a digital printer because holes transiting the CTL experience mutual Coulombic repulsion [39.12, 107]. It has been shown that for optimum resolution the photoreceptor thickness should be about one quarter of the pixel size [39.12, 13]. Thus, for 600-dpi imaging ($\approx 40\text{ }\mu\text{m}$ pixel size) the ideal photoreceptor is on the order of $10\text{ }\mu\text{m}$. Thin OPCs have not yet been introduced into digital printers but one might anticipate that this will occur as toners get smaller and the processes of toner transfer and fusing are refined to minimize image disruption [39.108].

39.4.2 Coating Technologies

Hopper coating of continuous webs and dip coating of drums are the two technologies commonly used to fabricate photoreceptors. As with any large-area photoelectrical device absolute cleanliness is required to prevent artifacts in the coated layers. In a multilayer device one must carefully control the interfaces between the layers. For example, a key interface is that between the CGL and CTL. Here it is important that the two layers adhere but do not mix to such a degree that the desired characteristics of either layer are compromised. Attaining the desired degree of mixing is a process of optimization depending on the materials, solvents, and coating method.

In hopper coating the coating solution is continuously pumped through a slot onto the moving web.

Film thickness is controlled by the pumping rate and solids content of the coating solution. Precise control of drying temperature, humidity, and air flow enable optimization of the coated layers. Curing of the coated film involves removal of solvent and annealing of the polymer binder(s). In a hopper coating process several layers can be coated in a single pass with sequential hoppers as long as the previous layer is adequately cured. Hopper coatings can be carried out at a very high speed (m/s) to produce a roll of many thousands of feet. To coat subsequent layers the previously coated substrate is re-run through the coating machine. Because the hopper coating process involves contact of the coated surfaces, and winding of the coated web, there is the possibility of film damage. Final inspection for film defects must be carried out and damaged, or imperfectly coated, regions must be removed before construction of the final photoreceptor loops.

In a dip coating process the substrate and coated layers are dipped into a solution or dispersion of the next layer to be coated and slowly withdrawn and cured. The coated layer thickness is determined by the rheological characteristics of the coating solution and the rate of withdrawal. Under these conditions there is the opportunity for extensive interaction between the previously coated layer and the solution into which it is dipped. Thus, formulations which are suitable for hopper coating may be inadequate for dip coating even though the chemical compositions of the final coated layers might be identical after curing. Another consideration with dip coating is that components of the previously coated layers which are soluble in the solvent used in the subsequent dip will contaminate the dip reservoir. Low levels of contamination may be insignificant, but since the amount of fluid removed in each coating operation is a small fraction of the total volume one must make sure that such contamination does not degrade performance.

Other processes such as ring coating (a dipped drum is withdrawn through an annulus which acts as a doctor blade to control the wet coating thickness), spray coating, vacuum coating, etc. may be used for specific applications and materials. In all layers coated from solution it is often necessary to add a small quantity of surface-active agent as a coating aid to enable smooth, defect-free coatings.

In the following sections we will discuss details around the compositions of each of the layers which might be found in an organic photoreceptor for electrophotographic printing. The order of discussion is in the order in which the typical photoreceptor would be constructed: substrate and ground layer, smoothing

layer and charge-blocking layer, charge-generation layer (CGL), charge-transport layer (CTL), and protective overcoat layer.

39.4.3 Substrate and Conductive Layer

A common element to all electrophotographic photoreceptors is a substrate on which all the layers are deposited. In a research environment a small square of glass or quartz is convenient, but in commercial applications the substrate is invariably either a polymer film or a metal drum. Some of the material characteristics which might be considered in the choice of a polymer film are: stiffness, toughness, transparency, core set, and surface friction. Polymeric photoreceptor substrates are often 3–7 mil. A common polymer film material is the polyester poly(ethylene terephthalate) (PET). PET film is very durable, optically transparent, and readily available in a wide range of thickness. Since it is highly insulating it must be coated with a conductive material to act as the ground plane. PET or other polymer films are available in large rolls and the coating operations are usually done on the roll rather than cut-to-size sheets. Although a solution-coated conductive layer is possible, the most common ground layers are metals such as Ni, Al, Cr, and Ti, which are applied in a continuous sputtering or similar vacuum technique. The metallized rolls are subsequently coated with the photoconductive layers.

If a metal drum is the chosen substrate it is almost invariably aluminium (1–10 mm wall thickness). The conductive metal serves as the ground layer but typically it receives further treatment before coating the photoconductive layers. The treatment may be chemical such as anodization to form a thin hole-blocking layer, or physical such as turning or sanding. Because these secondary surface treatments add cost, a smoothing layer is often used instead.

The electrical conductivity requirements of the conductive layer are modest. The higher the process speed the greater the conductivity required for adequate surface charge accumulation. Analysis by Chen [39.109] demonstrated that the result of inadequate conductivity in corona charging of a photoreceptor is a nonuniform surface potential. The surface potential is decreased depending on the distance from the actual grounding contact. For a typical situation the upper limit of the sheet resistance is $\approx 10^4 \Omega$ per square.

Alternative approaches such as *seamless* webs and conductive plastic drums have been developed but have not yet been commercialized.

39.4.4 Smoothing Layer and Charge-Blocking Layer

For xerographic applications it is important that the conductive layer does not inject charge into the photoreceptor in the dark. However, the metals used as grounding layers all have the potential to inject holes into the photoreceptor CGL via direct contact with the charge-generation material or the hole-transport material. The injection and transport of charge in the dark would cause a loss of surface potential (dark decay). Since the formation of a latent image relies on a difference between the rate of dark- and light-induced surface potential decrease, a high dark decay rate means that the process must be amenable to a small imaging potential. Another aspect of dark injection from the conductive layer is that such phenomena often occur in small localized *charge-deficient spots*. In a process where the discharged areas are developed small deposits of toner are found in what should be non-toned background. To counter such processes it is common to interpose a charge- (typically hole-) blocking layer between the ground layer and the CGL. With drum photoreceptors it may be the roughness of the metal surface which initiates the charge injection. In this case it may be necessary to interpose a relatively thick *smoothing layer* between the metal surface and the CGL.

In principle, any good film-forming insulating material will suffice as a charge-blocking layer as long as adhesion to the ground layer and CGL are adequate. Several types of materials have been used for this purpose including polysiloxanes and nylons. Since these materials are insulating, in an electrophotographic charge/expose cycle there will be a residual potential due to the field remaining across the layer. This will build up with cycling depending on the layer conductivity and the process cycle time. Although residual potentials typically decrease when the photoreceptor is rested in the dark, in practice such relaxation is usually incomplete and in subsequent cycling the residual builds up at a faster rate. The physics and chemistry of such hysteresis is not well understood. At some point the residual potential may cause image degradation and necessitate photoreceptor replacement. Thus, the blocking layer must be thick enough to cover the ground layer uniformly but not so thick as to cause an undesirable residual potential. Generally such a layer is coated at around $1 \mu\text{m}$ or less.

With an aluminium drum a thin anodized layer may prevent charge injection. However, making the drum surface smooth on a submicron scale is expensive

and an alternative is to use a relatively thick smoothing/blocking layer to cover the surface irregularities. Smoothing layers are typically metal oxides (titanium for example) in a polymer binder. The oxide loading is high to impart sufficient conductivity to prevent a residual potential. If the metal oxide does not inject holes it also serves as the charge-blocking layer. Such layers are up to around 10 μm thick.

Imaging with monochromatic radiation in digital printers has led to a new imaging artifact caused by interference between the incoming and reflected light. In dual-layer OPCs with the CTL uppermost, if the CGL incompletely absorbs the exposing light it can be reflected from the ground layer. The interference pattern that is produced can be visible in the developed image as a *wood grain* pattern. One way to counter this is to scatter the incoming light before it's reflected. There are many patents describing techniques for carrying this out including roughening of the surface of the conductive layer.

39.4.5 Charge-Generation Layer (CGL)

The CGL is where the imaging light is absorbed and charges are generated. The first major consideration in choice of material is that it strongly absorb the wavelengths of light emitted by the exposure system. In copiers light is reflected from a document onto the charged photoreceptor. Since an original may have colored components the light source must cover the visible range (400–700 nm) and the photoreceptor must have broad sensitivity to visible light. Common light sources in copiers are fluorescent or xenon lamps. Both sources are generally filtered to remove ultraviolet and infrared light. In digital printers the exposing source may be an LED array (680–780 nm) or a scanned laser (633 nm from He–Ne or 740, 780, and 820 nm from laser diodes).

Most modern commercial photoreceptors utilize pigments as charge-generation materials. Pigment-based CGLs comprise submicron crystals of the charge-generation material suspended in a polymer binder. Pigments are milled to the desired size and stabilized with appropriate additives and binders to produce a coating dispersion. Charge-generation materials are generally classified according to their chemical identity. Materials which absorb primarily in the visible region are dye-polymer aggregate, PVK–TNF charge-transfer

Fig. 39.13 Sensitivity action spectra of visible sensitive OPCs. The chemical structures of the CGL materials are given in Fig. 39.15

Fig. 39.14 Sensitivity action spectra of near-infrared sensitive OPCs. The chemical structures of the CGL materials are given in Fig. 39.16

complex, perylenes, and bisazos. Phthalocyanines, trisazo, and squarylium pigments are utilized for near-infrared absorption. Figures 39.13 and 39.14 show the sensitivity action spectra and Figs. 39.15 and 39.16 the chemical structures of these charge-generation materials. The sensitivity action spectra in these figures are taken from literature data and the sensitivities converted into consistent units ($\text{V}/\text{cm}^2/\text{erg}$) based on information given in the cited publication. Because the data are from OPCs with different thickness, exposure intensity, exposure time, initial potential, and exposed potential, the sensitivities are not directly comparable. However, the wavelength ranges are accurate. When the exposure is through the CTL (in a negative-charging dual-layer OPC) the photosensitivity will be decreased at wavelengths below $\approx 400\text{ nm}$ because of light absorption by the transport material.

Fig. 39.15 Chemical structures of visible sensitive charge generation materials

Perylenes, azos, and phthalocyanines are best known for their use as colorants and it is because these materials were readily available that they were investigated as charge-generation materials. A complication with pigments is that some exhibit polymorphism. Over many decades the colorant industry has developed technologies for controlling polymorphism to obtain pigments with specific colorant characteristics and similar technologies have been recently developed to obtain

Fig. 39.16 Chemical structures of near-infrared sensitive charge generation materials

polymorphs with the appropriate absorption as well as charge-generation characteristics for electrophotographic applications. Thus, in many cases to prepare a CGL it is first necessary to convert the pigment-generation material into a dispersion of submicron particles of the desired polymorph. Examples of charge-generation materials are discussed below.

The donor-acceptor charge-transfer (CT) complex between poly(N-vinyl carbazole) (PVK) and 2,4,7-trinitrofluorene-9-one (TNF) was the first commercialized organic photoreceptor [39.110, 111]. The photoconductivity characteristics have been extensively studied [39.79–81, 84–86] and reviewed [39.112–115]. With the addition of TNF the carrier-generation efficiency of PVK is increased and extended into the region of CT complex absorption. Based on field quenching of exciplex fluorescence a mechanism for PVK-acceptor systems was proposed involving carrier generation from a nonrelaxed exciplex which is accessed by either direct absorption into the CT state or via an encounter complex between excited PVK and TNF [39.84–87]. As used in the IBM copiers I and II a 1 : 1 molar ratio of PVK to TNF was coated as a single 20- μm layer and electron-dominated transport was used to create the latent image (negative surface charge) with a He-Ne laser exposure (632.8 nm) [39.111]. An exposure of 5.5 $\mu\text{J}/\text{cm}^2$ was used to decrease the surface potential from -750 to -200 V. The quantum efficiency based on incident photons was ≈ 0.2 while the maximum efficiency was ≈ 0.3 at ≈ 400 nm. The photosensitivity action spectrum for this OPC is shown in Fig. 39.11 [39.110]. Using the photoinduced discharge technique [39.82] the maximum quantum efficiency (charges transported through the device per photon absorbed) was found to be 0.14 at 375 nm and a field of 10^6 V/cm. The PVK-TNF-based OPC had several drawbacks: low photosensitivity, short lifetime in the electrophotographic process, and concerns about the safety of TNF. It was eventually replaced with dual-layer OPCs with CGL materials based on pigments. Acceptor-doped PVK continues to receive attention particularly with C_{60} and related molecules as the acceptor [39.116].

The dye-polymer-aggregate based CGL is unique in that the active material is formed in situ during the coating process. A solution of thiapyrylium dye (2,6-diphenyl-4(4-dimethylaminophenyl)thiapyrylium perchlorate) and bisphenol-A polycarbonate is coated to form a CGL in which the dye and polymer spontaneously aggregate [39.117–119]. The aggregate is a dense filamentary structure which has an absorption spectrum red-shifted from that of the dye. The aggregate filaments

transport electrons with high field trapping due to carrier immobilization at filament dead ends. The photosensitivity of the aggregate is several orders of magnitude larger than that of the nonaggregated dye [39.120]. To prepare a CGL the formulation also includes hole-transporting materials. Because the CGL transports both holes and electrons it is possible to use the aggregate as a single layer or as the CGL in a dual-layer photoreceptor. Because the aggregate absorption drops rapidly at wavelengths longer than 700 nm this material is only useful for visible-light exposure systems, Fig. 39.13. In this example the CGL (2 μm) comprised dye and tri-*p*-tolylamine (TTA) hole-transport material in polycarbonate, and the CTL (13 μm) was a solid solution of 40 wt % tri-*p*-tolylamine in a polyester binder [39.88]. This was charged to -600 V and exposed with very low-intensity continuous irradiation to obtain the initial rate of photodischarge. At 680 nm the photogeneration efficiency is 0.34 per absorbed photon. The quantum efficiency (Onsager model) was 0.6 and the thermalization distance was dependent on the concentration of hole-transport material ranging from 200 nm (5 wt %) to 600 nm (40 wt %) [39.88], Fig. 39.11.

Azo compounds contain the $-\text{N}=\text{N}-$ functionality. Bisazo compounds have the general structure $\text{R}'-\text{N}=\text{N}-\text{R}-\text{N}=\text{N}-\text{R}''$. Trisazo compounds have the general structure $\text{R}(-\text{N}=\text{N}-\text{R}')(-\text{N}=\text{N}-\text{R}'')(-\text{N}=\text{N}-\text{R}''')$. The R substituents generally have extended conjugation to provide the colors which have made bisazo compounds important dyes and pigments for many years. Bisazo CGLs generally absorb in the visible and trisazo into the near-infrared. An early example of a bisazo pigment-based OPC (chlorodiane blue, 4,4'-bis(1''-azo-2''-hydroxy-3''-naphthylidene)-3,3'-dichlorobiphenyl) was used in the IBM 3800 printer. This photoreceptor had over four times the photosensitivity of the PVK-TNF-based OPC [39.121]. Azo charge-generation materials are often synthesized from the reaction of an aromatic amine with an o-hydroxyaromatic carboxylic acid such as naphthol-AS. As CGL materials these materials are used as dispersed pigments. Although bisazo pigments do not generally exhibit polymorphism they can exist as hydroxy-azo or keto-hydrazone tautomers. In some cases, it has been found that the active form is the keto-hydrazone tautomer [39.122]. Because the synthesis of azo compounds is relatively easy there is a considerable literature on the effects of chemical structure on electrophotographic characteristics and carrier-generation efficiency [39.123–127]. In azo pigments charge is generated extrinsically with the pigment

exciton oxidizing a hole-transport molecule at the pigment surface [39.127, 128] and it was demonstrated that penetration of the CTL into the CGL occurs during the coating process [39.129]. The photosensitivity action spectrum for a fluorenone bisazo pigment is shown in Fig. 39.13 [39.128]. In this OPC the CGL ($0.17\text{ }\mu\text{m}$) consisted of the pigment in a binder of poly(vinyl butyral) (10 : 4 weight ratio) and the CTL ($17.4\text{ }\mu\text{m}$) a solid solution of hydrazone transport material, *p*-diethylaminobenzaldehyde diphenylhydrazone (DEH), in polycarbonate (9 : 10 weight ratio). The initial potential was -800 V and the exposure required for a discharge to -400 V determined. The quantum yield of carrier generation from the Onsager model was 0.52 with a thermalization length of 1400 nm . Time-resolved transient absorption spectroscopy has been used to study the formation and decay of the oxidized transport material [39.130]. With a bisazo-based CGL (chlorodiane blue) [39.131] and trisazo-based CGL it was found that the charge-generation efficiency depended on the oxidation potential of the CTL transport materials [39.125]. In the most favorable case the bisazo had a quantum efficiency of 0.25 and the trisazo about 0.5. This was interpreted in terms of the energy gap between the hole at the pigment surface and the transport material. In a study using a series of bisazo pigment CGLs and a common CTL it was found that neither electron donating nor withdrawing substituents favor high photosensitivity [39.126]. Photosensitivity was found to depend inversely on the crystallinity of the pigment, which was interpreted in terms of pigment surface area. The development of high-sensitivity azo-based CGLs has been reviewed by Murayama [39.132]. The trisazo pigment-based OPC has an absorption which extends into the near-infrared, making it suitable for laser exposures. Figure 39.14 shows the photosensitivity action spectrum of an OPC with a trisazo pigment CGL [39.133]. The CGL ($0.33\text{ }\mu\text{m}$) consisted of the pigment in poly(vinyl butyral) binder (10 : 4 weight ratio) and the CTL ($18.5\text{ }\mu\text{m}$) was a solid solution of DEH transport material in polycarbonate (9 : 10 weight ratio). The initial surface potential was -700 V and the exposure to discharge to -300 V used to determine the photosensitivity at each wavelength. A photoreceptor with CGL ($0.12\text{ }\mu\text{m}$) and CTL ($19.5\text{ }\mu\text{m}$) had a quantum efficiency for charge generation of 0.46 from $500\text{--}800\text{ nm}$ [39.133].

Perylenes used as CGL materials are diimides of perylene-3,4,9,10-tetracarboxylic acid. One example is the *N,N'*-bis(2-phenethyl)-perylene-3,4:9,10-bis(dicarboximide). In this case the CGL was prepared

by vacuum deposition of an amorphous film ($0.1\text{ }\mu\text{m}$). Exposure to dichloromethane (as when overcoating with the charge transport layer) converts the film into a crystalline form with enhanced absorption at 620 nm [39.135]. The mechanism of carrier generation of this pigment in the presence of tri-*p*-tolylamine has been studied by studying the field dependence of quenching of perylene fluorescence [39.136]. The results were interpreted in terms of both intrinsic (directly from the perylene singlet state) and sensitized (interaction of holes on the pigment surface with the amine) charge generation. More recently, a bisbenzimidazole perylene has been developed as a CGL [39.137–139]. Dual-layer OPCs with a CGL of $0.1\text{-}\mu\text{m}$ vacuum-deposited bisbenzimidazole perylene, and a $15\text{-}\mu\text{m}$ CTL of 35 wt % TPD in polycarbonate, exhibit high sensitivity ($E_{1/2}$ 2 erg/cm^2 for -800 V_0) out to 700 nm , Fig. 39.13. Recent research has involved the synthesis and study of novel materials such as dimeric perylene pigments [39.140].

Phthalocyanines have received considerable attention as CGL materials for near-infrared exposure systems. Metal-free (H_2Pc) [39.141–144], titanyl (TiOPc) [39.134], and hydroxygallium (HOGaPc) [39.145] phthalocyanines have been extensively stud-

Fig. 39.17 Absorption spectra of polymorphs of TiOPc. After [39.134]

ied as CGL pigments. Although these materials are relatively easy to synthesize their intractability makes them difficult to purify. Except for halogen substituents on the aromatic rings there has been little research into the effect of chemical structure on performance. Instead, much of the development has been to understand and control polymorphism. Compared with solution absorption spectra, the spectra of many CGL pigments are broadened with enhanced absorption in the red and near-infrared. With specific combinations of milling technique, solvent exposure, and thermal treatment many phthalocyanine polymorphs can be produced [39.146–148]. Polymorphs have been characterized by visible and near-infrared absorption spectroscopy, X-ray diffraction, nuclear magnetic resonance (NMR) spectroscopy, infrared spectroscopy, and infra-red (IR) absorption spectroscopy. Examples of TiOPc polymorph absorption spectra are shown in Fig. 39.17 [39.134]. Polymorphs may have very different photogeneration characteristics as CGLs in OPCs. The materials shown in Fig. 39.17 were fabricated into OPCs: CGL, 0.4 μm , pigment and poly(vinyl butyral) 1 : 1 weight ratio; CTL, 20 μm , 43 wt % triarylamine hole-transport material, 4-(4-methylstyryl)-4',4''-dimethoxytriphenylamine, in polycarbonate. The photosensitivity action spectra for OPCs from the Y- and A-forms of TiOPc are shown in Fig. 39.14. The OPC with the Y-form had a photosensitivity for half photodischarge (600–850 nm) of 0.75 erg/cm² (initial potential –600 V) while the A-form was much less sensitive. In another study, photoreceptors formulated with α -, β -, τ -, and X-forms of H₂Pc had generation efficiencies as follows (5×10^5 V/cm): $\tau_2 \approx 0.1$, $X_2 \approx 0.09$, $X_1 \approx 0.03$, $\beta_1 \approx 0.01$, $\alpha_2 \approx 0.005$, and $\alpha_1 \approx 0.001$ [39.149]. In the preparation of a generation material a common procedure is to prepare the pigment in the amorphous form by acid pasting or with a specific milling technique, and then to convert the pigment to the desired polymorph with a specific solvent treatment. The desired polymorph must of course be stable to all the subsequent operations. In addition to the dominant influence of crystal form on electrophotographic performance, recent studies have implicated water in carrier generation of Y-form TiOPc [39.134, 150]. A recent paper has reviewed the carrier generation mechanisms in several phthalocyanines [39.151]. In all the pigments studied [x -H₂Pc, TiOPc (I) (low sensitivity), TiOPc (IV) (also known as Y, high sensitivity), HOGaPc (V)], fluorescence quenching implicates a neutral excited state (not a charge-transfer state) as the precursor to carrier generation. Studies of

the effect of field on fluorescence amplitude and lifetime reveal that with HOGaPc and TiOPc (I and IV) carrier generation comes from a non-relaxed excited state and TiOPc (IV) has an additional generation channel from a trapped state. With x -H₂Pc trapped excitons appear to be the major source of charge carriers.

Squarylium (squaraine) pigments are a class of materials which were first synthesized only recently. Squaryliums [2,4-di-(*o*-hydroxy-*p*-dimethylaminophenyl)cyclobutene and 1,4-bis-(4-dimethylamino-2-methylphenyl)diylum-1,3-diolate] were the first pigments to be utilized as a near-infrared-sensitive CGL in an IBM printer [39.131, 152, 153]. The photoreceptor based on the hydroxy squarylium with a CTL (21 μm , DEH in bisphenol-A polycarbonate) had high photosensitivity from 500–800 nm (≈ 3 erg/cm² for a –700 to –200 V photodischarge), Fig. 39.14 [39.153]. This class of pigment has been extensively investigated for use as pigment-dispersion CGLs for near-infrared exposure systems [39.137, 154–160]. A nonsymmetrical squaraine (UFSq)-based OPC with CGL, 0.4- μm UFSq in poly(vinyl formal) (80 : 20 weight ratio), and CTL 26- μm 40 wt % TPD in bisphenol-A polycarbonate, exhibited an $E_{1/2}$ photosensitivity of 1.9 erg/cm² at 790 nm ($-980 V_0$) when optimally purified [39.160], Fig. 39.14.

39.4.6 Charge-Transport Layer (CTL)

In all current commercial organic photoreceptors holes are the carriers that dominate photodischarge of the device. Hole transport is carried out by aromatic amines which are either doped into, or are incorporated as part of, the binder polymer. The key molecular characteristic is that aromatic amines have relatively low oxidation potentials. The oxidation potential of the transport moiety must be lower than that of the charge-generation material such that photogenerated holes are injected from the generation material into the charge-transport layer. In a chemical sense the key reaction is oxidation of the charge-transport material by the photogenerated hole on the surface of the generation material. If the oxidation potential of the transport material is too low it will undergo air oxidation, if it is too high its oxidation will require an activation energy and will be inefficient. Molecular orbital studies suggest that molecules with little change in geometry with oxidation will be favorable for hole transport [39.161]. Aromatic amines with oxidation potentials between about 0.8–1.2 eV (relative to SCE) are generally useful as hole-transport materials. The synthesis and study of hole-transport molecules

is a very active area. Figure 39.4 shows the chemical structures of some common hole-transport materials: 1,1-bis(*p*-diethylaminophenyl)-4,4-diphenyl-1,3-butadiene (DPB), *p*-diethylaminobenzaldehyde diphenylhydrazone (DEH), tri-*p*-tolylamine (TTA), N,N'-diphenyl-N,N'-bis(3-methylphenyl)-(1,1'-biphenyl)-4,4'-diamine (TPD), and 1,1-bis(di-4-tolylaminophenyl)cyclohexane (TAPC). These are often referred to by acronym and classified according to one of their structural functionalities: arylmethane, diarylamine, enamine, triarylamine, heterocyclic, butadiene, and hydrazone. A more complete listing is available in *Borsenberger and Weiss* [39.4].

Charge transport was discussed previously (Sect. 39.2.2). Since transport involves orbital overlap between neighboring charge-transport moieties their concentration needs to be as high as possible. In practice, molecular transport materials are doped, singly or as a mixture, at 40–50% by weight into the binder polymer. The purpose of the binder polymer is to provide an inert, robust, substrate for the transport material. The mobility characteristics of a large number of hole-transport materials have been studied and the results interpreted according to a model where the dissolved transport molecules are disordered in energy and position [39.162–164]. Binder effects on hole transport have been observed. It appears that the presence in the CTL of materials with highly polar substituents decrease hole mobility but in general these effects are not well understood [39.165–170].

Since the CTL is typically the surface that is exposed to the various electrophotographic process elements it must be formulated to resist damage and wear. The glass-transition temperature (T_g) of the CTL is an important characteristic. Too low and the material will be soft and easily damaged, too high and it will be brittle. Generally a T_g around 60 °C is adequate. Polycarbonates and polyesters are two classes of materials commonly used as CTL binder polymers.

Dual-layer devices in which electron transport dominates have been studied extensively but never commercialized. Examples of commercialized electron-transport-dominated photoreceptors are the single-layer dye-polymer aggregate and the PVK-TNF charge-transfer complex. Electron-transport materials are designed to be easily reduced. The reduction potential must be lower than that of the photogenerated electron on the charge-generation material so that it is transferred to the transport material. However, it is believed that oxygen may act as an electron trap so the reduction potential of the transport material must be lower than

that required to reduce oxygen dissolved in the polymer film. Figure 39.10 shows the chemical structures of some electron-transport materials. As with hole-transport materials acronyms based on molecular functionality are common: 1,1-dioxo-2-(4-methylphenyl)-6-phenyl-4-(dicyanomethylidene)thiopyran (PTS), *n*-butyl 9-dicyanomethylenefluorene-4-carboxylate (BCMF), 2,4,7-trinitro-9-fluorenone (TNF), 3,3'-dimethyl-5,5'-di-*t*-butyl-4,4'-diphenoquinone and 3,5'-dimethyl-3',5-di-*t*-butyl-4,4'-diphenoquinone isomer mixture (DPQ); a more complete table can be found in *Borsenberger and Weiss* [39.4]. In general the charge mobilities observed with electron-transport materials are much lower than for hole-transport materials. For this reason dual-layer OPCs with electron-transport-based CTLs have not been commercialized. Analysis of the mobility characteristics of electron transport with the disorder model implicates the highly polar nature of all electron-transport molecules [39.171–174].

Both hole- and electron-transport materials have been prepared with the transport moieties as part of a polymer (main chain or pendant) which would serve as a binder with hole-transport functionality. The advantage of a transport-active polymer is that it is a single material. In practice, charge transport is generally not enhanced in these materials and their chemical complexity makes them expensive to synthesize. Other than PVK, molecularly doped polymers are the current choice for CTLs.

39.4.7 Backing Layer

In a web photoreceptor the substrate-photoreceptor may tend to curl due to the residual stress of the coated layers. Such curl can make it difficult to fabricate the web into loops, may degrade loop tracking in the machine, or cause the loop edge to touch other process elements. Any of these attributes would make the photoreceptor unusable. One way to counter film curl is to coat a polymer layer on the back side to compensate for the stresses in the photoreceptor layers. The back-coat polymer must have adequate physical characteristics (friction, wear, etc.) to withstand cycling in the process. The extra coating adds expense but its addition is relatively commonplace. Any suitable polymer, such as a polycarbonate, may be used.

39.4.8 Overcoat Layer

Overcoat layers have received increased attention to lengthen the photoreceptor life by preventing wear, min-

imizing the effects of surface contacts, the effects of corona effluents (ozone and nitrogen oxides), and liquid attack in liquid-toner-based printers. As with the charge-blocking layer, the simplest approach is to coat a thin insulating polymer onto the photoreceptor surface. The thickness cannot be more than a few μm if one wants to avoid large residual potentials. Several approaches have been developed. One approach is to coat a second CTL with a changed composition to maximize polymer toughness (often by lowering the concentration of transport material). Other approaches are to overcoat the photoreceptor with a silsesquioxane sol-gel several μm thick, or with a submicron refractory layer of diamond-like carbon or silicon nitride.

Silsesquioxane overcoats applied in a sol-gel process have received recent attention [39.175, 176]. One commercial application utilized a sol-gel to overcoat a photoconductor with an uppermost CGL (positive-charging OPC). Because the CGL is sensitive to wear

and corona chemicals an overcoat was essential to its implementation in a commercial photoreceptor. The sol is prepared and subsequently hopper-coated and cured at elevated temperature to effect crosslinking. To avoid residual potential some conductivity is necessary but this cannot be so high that the latent image is degraded [39.177].

A polyurethane overcoat in a positive-charging dual-layer OPC has recently been described for use in a liquid-toner-based printer [39.178]. The CGL was based on TiOPc pigment and, to avoid disruption of the CGL during the overcoat coating operation, an aqueous polyurethane dispersion was used.

Diamond-like carbon, silicon nitride, and other [39.179] overcoats are applied in a vacuum process as submicron layers. Although tough, their thinness limits their utility for scratch and wear resistance. Furthermore, depending on their chemical make up they may have sensitivity to corona gasses.

39.5 Photoreceptor Fabrication

As discussed above the two most common photoreceptor configurations are as a loop or a metal drum. After coating the layers of a drum photoreceptor it is ready to use in the process. Generally the drums are inspected for visible defects and samples are taken for process testing and quality control. Since the substrate is conductive the ground contact is easily made by means of a conductive brush contacting the edge or inside of the drum when it is mounted in the machine. On the other hand, after the appropriate layers are coated on a web several more steps are required for fabrication of the photoreceptor. The web is rolled onto a spool at the end of the coating process and subsequently slit to the desired width and rewound. The coated roll is then inspected for visible defects and defective areas are marked for removal. Defective areas are removed when the photoreceptor is cut to the desired length. The cut sheets are then ultrasonically welded to produce a photoconductor loop. Because the conductive layer is buried between the substrate and the coated layers, making a ground contact is not trivial. It is possible to leave one edge of the ground layer uncoated but, because the thin metal would be readily damaged or worn away with use, one typically finds a conductive stripe coated on one edge of the photoreceptor. The only requirement is that the conductive stripe penetrate the coated layers and contact the metal. The ground contact in the machine is often

made with a conductive brush contacting the conductive stripe. The printing machine must keep track of the splice for several reasons: cleaning blade, degraded photoconductivity due to the ultrasonic welding, etc. This is sometimes accomplished by applying marks to the back of the photoreceptor, which are detected by the machine.

Fabricating a photoreceptor loop entails several operations not required in the fabrication of drum photoreceptors (slitting, cutting, conductive striping, welding, backside marking, etc.). Web-coating a photoreceptor is an expensive process but many thousands of feet of photoreceptor can be produced in a single coating event. Furthermore all the loop-processing elements are relatively straightforward and inexpensive. The key factor is that web-coating is a continuous process while drum-coating is a batch process. Photoreceptor loops are generally about 10 \times less costly to produce than drums.

There are advantages and disadvantages to both seamed loop and drum configurations in a printing machine. Loops can be made small for desktop printers or large for high-speed commercial printers. A large web (current commercial webs are as large as ≈ 10 feet in circumference) provides more surface area for imaging (several images per loop cycle) and more space for the various electrophotographic process elements. In addition, exposures through a semitransparent conductive layer are possible. Disadvantages are the presence of

a seam which must be tracked and makes some processes, such as cleaning with a blade, problematic. Also, the tendency of a web to flutter or move necessitates both tracking and positioning to achieve adequate print registration. Metal drums are seamless and rigid, making it easier to control drum position. However, drums

typically have a diameter of 35–300 mm and have limited imaging area and space for process elements. All things being equal a loop which produces several images per cycle will produce more images over its lifetime than a drum. Ultimately, the choice of loop or drum is a printing system issue.

39.6 Summary

Organic photoreceptors have been utilized in electrophotography since 1970. In this chapter we have briefly reviewed the development of organic photoreceptors from the standpoint of the device architecture, materials formulation, and electrical characteristics with emphasis on how the materials used impact on specific device functions.

The use of organic materials has enabled the development of electrophotographic technologies into a multi-billion-dollar business. Today's organic photoreceptor is a large-area photoelectric device capable of very high spatial resolution in the formation of a large-area image, with pixel resolution as small as 20 μm (1200 dpi), to meet demanding image-quality requirements. It is truly an amazing success story. Many of the principles and indeed many of the same materials are being applied to today's highly publicized new technologies including organic light-emitting diodes (OLED) and organic transistors. In this chapter we have described the device requirements and shown how organic photoreceptor development has progressed through a combination of architecture manipulation and materials design.

Organic photoreceptors have to satisfy many diverse requirements to be successfully employed in electrophotography as it is practiced today. These requirements have been met in large part by the principles of: (1) functional separation, and (2) materials design for the enhancement of specific electrical and mechanical characteristics. The concept of functional separation was key to organic photoreceptor development. Rather than try to produce a device with all the desirable characteristics in a single layer it is more productive to have a multi-layer architecture with each layer being optimized for a specific characteristic. Not surprisingly these layers are commonly named after those characteristics which are paramount: the charge-generation layer (CGL), the charge-transport layer (CTL), the charge-blocking layer, the protective overcoat layer, etc. In this chapter we have described the characteristics of each of these layers and

demonstrated how materials have been chosen and new materials synthesized to optimize their characteristics.

It is worthwhile to take a minute to review the electrophotographic process and consider the characteristics which have been built into the device.

- **Spatial uniformity.** The thickness of each of the coated layers (each varies from submicron to a few tens of μm) and the total thickness (controlled mainly by the CTL) must be very uniform so that the device capacitance (a major factor in determining surface charging characteristics) is uniform (on the order of a few percent variability). The CGL generation characteristics must be uniform, which means that the optical density of the CGL at the exposure wavelength must be uniform, to produce a uniform surface potential after exposure (on the order of a few percent variability). Thickness must be uniform for the smallest pixel (20 μm for 1200-dpi imaging) over the entire area of the device ($> 1000 \text{ cm}^2$). The ability to coat large areas of such thin layers to this degree of uniformity is a great technological achievement.
- **Chemical resistance.** Photoreceptors must resist chemical attack. Because corona charging is the most common method of applying a surface potential, the photoreceptor must be stable to the acid and oxidizing species produced in the corona. These chemicals (ozone, NO_x , and HNO_x) are highly reactive and the layer that is exposed (usually the CTL) must not be degraded. This is achieved by judicious choice of materials, the addition of stabilizers (antioxidants) to the CTL, or a protective overcoat.
- **Electrical uniformity and stability.** The photoreceptor dark electrical and photoelectrical characteristics (surface potentials with no exposure, imaging exposure, and erase exposure) must be very uniform and stable to prolonged electrophotographic cycling. The initial (dark) and exposed potentials must be the same for each pixel over the entire device area and

must remain stable with cycling. If these characteristics drift uniformly with cycling, machine process control must be implemented to maintain image quality. If these characteristics drift nonuniformly the photoreceptor must be discarded when image artifacts (ghosting) appear.

- **Photosensitivity.** The sensitivity of the photoreceptor to light, often expressed as the energy needed to produce a defined decrease in surface potential, must be mated with the exposure used in the process in terms of exposure energy and wavelength. This has been achieved by the synthesis and pigment form manipulation of charge-generation materials. Today's high-sensitivity photoreceptors can approach a quantum efficiency of unity for charge generation (at a typical applied field of ≈ 20 V/cm). But, most importantly photoreceptors with lower sensitivity can be fabricated depending on the needs of the imaging system.
- **Photodischarge rate (switching time).** The time it takes for photogenerated carriers to transit the device limits the printing process speed. With the synthesis of highly stable hole-transport materials and the principle of molecularly doped polymers it has been possible to prepare devices with hole transit times that permit printing speeds approaching 200 pages/min.
- **Mechanical strength.** The surface of the photoreceptor that is exposed to the abrasive process elements

(often the development and cleaning systems), must not wear too rapidly or unevenly and must be stable to crazing or other forms of damage. Typically the CTL is the surface layer, and considering that it is typically a polymer with as much as 50% by weight of charge-transport molecules, it is remarkable that materials can be chosen such that significant wear occurs only after tens of thousands of cycles. Where warranted, very tough protective overcoats have been developed which have little effect on the overall OPC device performance.

Today multilayer organic photoreceptors that meet all of the requirements listed above are made commercially on a huge scale. This success is due in large measure to the skill of the scientists and engineers who design the materials and processes for photoreceptor fabrication, and who then integrate it into the electrophotographic printing system such that acceptable and consistent image quality is obtained for a photoreceptor life, which is routinely 200 000 imaging cycles or longer if protective overcoat layers are used. This is an amazing story, an organic photoreceptor device with *adjustable* sensitivity at any desired wavelength from the visible to the near-infrared, with stable dark and photoelectrical characteristics over many thousands of imaging cycles, such that the characteristics of a 40- μ m pixel area are identical over an area which might be greater than 1000 cm².

Luminescent

40. Luminescent Materials

This chapter surveys the field of solid-state luminescent materials, beginning with a discussion of the different ways in which luminescence can be excited. The internal energy-level structures of luminescent ions and centres, particularly rare-earth ions, are then discussed before the effects of the vibrating host lattice are included. Having set the theoretical framework in place, the chapter then proceeds to discuss the specific excitation process for photo-stimulated luminescence and thermally stimulated luminescence before concluding by surveying current applications, including plasma television screens, long-term persistent phosphors, X-ray storage phosphors, scintillators, and phosphors for white LEDs.

Luminescent materials are substances which convert an incident energy input into the emission of electromagnetic waves in the ultraviolet (UV), visible or infrared regions of the spectrum, over and above that due to

black-body emission. A wide range of energy sources can stimulate luminescence, and their diversity provides a convenient classification scheme for luminescence phenomena, which is summarised in Table 40.1. Pho-

Table 40.1 Types of luminescence

Designation	Excitation	Trigger	Acronym
Photoluminescence	UV, visible photons	–	PL
Radioluminescence	X-ray, gamma rays, charged particles	–	RL
Cathodoluminescence	Energetic electrons	–	CL
Electroluminescence	Electric field	–	EL
Thermoluminescence	Photons, charged particles	Heat	TSL
Optically/photo-stimulated luminescence	Photons, charged particles	Visible/IR photons	OSL, PSL

Fig. 40.1 Optical pumping cycle for a generic photoluminescent system

toluminescence, where the luminescence is stimulated by UV or visible light, is a widely used materials science technique for characterising dopants and impurities, and finds applications in lighting technologies such as fluorescent lamps. Radioluminescence involves excitation by ionising radiation, and is used in scintillators for nuclear particle detection; the special case of stimulation by energetic electrons is called cathodoluminescence, the name arising from early atomic physics experiments involving gas discharges. The major application of cathodoluminescence is in cathode ray tubes for television sets and computer monitors. Electroluminescence involves collisional excitation by internal electrons accelerated by an applied electric field, and with a much lower energy than in the case of cathodoluminescence. Electroluminescence finds applications in panel lighting used in liquid-crystal display (LCD) back-planes, and in light-emitting diodes.

There are other forms of luminescence which we mention for completeness but will not discuss further: bioluminescence and chemiluminescence where the energy input is from chemical or biochemical reactions, sonoluminescence (sound wave excitation), and triboluminescence (strain or fracture excitation).

There are several books which describe the luminescence of materials in more depth than is possible in a short article, for example that edited by Vij [40.1] and the monograph by Blasse and Grabmaier [40.2].

The terms phosphorescence and fluorescence are often used in connection with luminescent materials. This classification is based on the time-domain response of the luminescent system. Figure 40.1 shows a generic photoluminescent system where incident UV radiation excites a system from a ground state 1 with probability per unit time P_{12} into an excited state 2. The system decays with probability P_{23} to a luminescing level 3, from which there is a probability P_{31R} and P_{31NR} of radiative and nonradiative decay, respectively, to the ground state. Nonradiative decay generally involves phonon emission.

First suppose that the transition probabilities are such that $P_{12}, P_{21} \gg P_{31} (= P_{31R} + P_{31NR})$. If the optical pumping (excitation) is abruptly stopped, the population of the luminescing state 3 decays as,

$$N_3 = N_3(0) \exp(-P_{31}t) \quad (40.1)$$

and the rate of luminescent energy emission is $-(h\nu P_{31R}/P_{31})dN_3/dt$ for an energy difference $E_{31} = h\nu$ between states 1 and 3. Hence the luminescence intensity at distance r from the sample is,

$$I = (h\nu) N_3(0) P_{31R} \exp(-P_{31}t) / (4\pi r^2) \quad (40.2)$$

and the characteristic luminescence lifetime is $\tau = (P_{31})^{-1}$. Thus the lifetime is governed by both radiative and nonradiative processes, whilst the intensity of the luminescence depends on the relative magnitude of P_{31R} .

This discussion provides the basis for understanding the terms fluorescence and phosphorescence applied to luminescent materials. A material is often classified as one or the other according to the relative magnitude of $\tau = (P_{31})^{-1}$, with 10 ns being set in a relatively arbitrary way as the boundary between a *fast* fluorescent system and a *slow* phosphorescent one. For comparison, the theoretical lifetime for spontaneous emission for a strongly allowed hydrogen atom $2p \rightarrow 1s$ transition is about 0.2 ns.

However, by this definition phosphorescence can also arise from luminescent states with short lifetimes which are populated through ones with long lifetimes. In Fig. 40.1, if state 2 is long-lived in the sense that $P_{23} \ll P_{31}$ then the measured lifetime for emission from the luminescing state will be $\tau = (P_{23})^{-1}$, and the system will be labelled phosphorescent, even though the luminescing level itself has a very short lifetime. In consequence, a second classification [40.2] is based on whether or not the luminescing level is fed by a metastable state which sets the lifetime. Sometimes the metastable state is a long-lived intermediate form

of energy storage which can be triggered by an external stimulus to undergo a transition to a fluorescent level. Thus in Table 40.1, thermally stimulated and optically stimulated luminescence involve a metastable state consisting of trapped electrons and holes, which can be triggered to recombine by heating or by optical

stimulation; the recombination energy is transferred to a fluorescing centre.

Overall, the fluorescence/phosphorescence classification is somewhat nebulous, and it is debatable whether the classification is necessary or desirable.

40.1 Luminescent Centres

A wide variety of centres give rise to luminescence in semiconductors and insulating materials, including rare-earth ions, transition-metal ions, excitons, donor–acceptor pairs, and ions with a d^{10} or s^2 electronic configuration ground state. Some luminescence spectra consist of broad emission bands arising from the interaction between the electronic system of the luminescent centre and the vibrations of the atoms or ions, which surround it; the broad bands arise from simultaneous transitions of both electronic and vibrational systems. For others, such as the rare earths, the spectra comprise sharp lines arising from purely electronic transitions, and the effect of the environment is felt mainly through their effects on the lifetimes of the states. Thus in discussing the physical background to luminescence, it is simplest to start with a discussion of rare-earth luminescence, where the effect of vibrations can be initially ignored.

40.1.1 Rare-Earth Ions

The trivalent rare-earth ions have n electrons ($n = 1 - 14$) in the $4f$ shell. In a free ion, the eigenstates resulting from the various atomic interactions are labelled by the total spin S and orbital angular momenta L . Spin–orbit coupling breaks up each L, S multiplet of degeneracy $(2S + 1)(2L + 1)$ into sub-multiplets labelled by the total angular momentum $J = L + S$, where J can range from $L - S$ to $L + S$. The $4f^n$ orbitals lie within the outer $5s^2$ and $5p^6$ filled shells, which partly shield them from the effects of a crystalline environment. The effects of the latter are quantitatively described by the *crystal field* [40.3], and this term in the Hamiltonian splits the J multiplets into $2J + 1$ sublevels, the so-called crystal-field splitting. Some of these crystal-field levels may still be two- or threefold degenerate, depending upon the symmetry of the environment. Odd-electron systems always have at least twofold (Kramers) degeneracy. The resulting energy-level structures are complicated, and are summarised in the classic *Dieke di-*

agram [40.3]. The original has been updated by *Carnall et al.* [40.4] and is reproduced in many books and papers on rare-earth ion spectroscopy [40.2]. In Fig. 40.2, we show a schematic version (not accurately to scale) of the diagram appropriate for Pr^{3+} with $n = 2$, which serves for our discussion. The crystal-field splitting is usually smaller than the spin–orbit splitting, and is illustrated schematically by the vertical extent of the bands in Fig. 40.2. The multiplet labels follow the usual $^{2S+1}L_J$ system.

In the figure we also show a generic highest excited band which does not belong to the $4f^2$ configuration. In the specific case of the rare earths this can be the excited-state configuration resulting from promo-

Fig. 40.2 Schematic energy-level diagram for Pr^{3+}

tion of one electron to the 5d state, giving an overall $4f^{n-1}5d^1$ configuration; more generally it could be a so-called charge transfer band, which corresponds to the transfer of one electron from the ligands to the luminescent ion. The relative location and importance of these bands varies with the luminescent ion and the crystalline environment, but they play an important role in the excitation of luminescence.

Excitation and luminescence transitions within the various levels in Fig. 40.2 are governed by the golden rule of quantum mechanics [40.5] for interactions with the electromagnetic field; in summary the probability of a transition between two states i and j is proportional to square of the matrix element $\langle i|H|j\rangle$, where H is the time-dependent perturbation Hamiltonian representing the interaction of the electrons with the electromagnetic field. The proportionality constant contains the light intensity in the case of excitation. The perturbation can be expanded in a power series involving electric and magnetic multipoles of the electronic system, but of these the electric dipole term is dominant, with the magnetic dipole term being much smaller by a factor of more than five orders of magnitude. Since the electric dipole operator \mathbf{er} has odd parity, the matrix element for transitions $r_{ij} = \langle i|\mathbf{er}|j\rangle$ is necessarily zero unless i and j have opposite parity. This is the most important selection rule governing luminescence: transitions between states of the same parity have zero transition probability and so are *forbidden* (Laporte's rule). In the case of the rare earths, all states of a single $4f^n$ configuration have the same parity, and so all optical transitions within the configuration are strictly forbidden. But this rule is relaxed by several considerations. First, if the crystalline environment lacks inversion symmetry, the crystal field admixes a small fraction of the excited configurations (eg $4f^15d^1$ for Pr^{3+}) of opposite parity into the ground configuration, which makes such transitions weakly allowed. Secondly, the selection rule for magnetic dipole transitions is that they are allowed between states of the same parity, although they are typically about five orders of magnitude weaker than for electric dipole ones. Finally, odd-parity vibrations and an electron-phonon interaction produce a similar configuration admixture effect to static lattice odd-parity mixing although this effect is more important for 3d ions than for 4f ones.

With only weak transitions possible within the 4f configuration, one might wonder how it would be possible to optically excite any significant luminescence. The answer lies in the 5d or charge-transfer bands which either lie at higher energies, or overlap with the upper levels of the 4f configuration. These give rise to strong

absorption and efficient pumping. Relaxation can occur via the parity-allowed transitions to the upper levels of the 4f configuration, and from there via single or multiple radiative emissions back to the ground state. Because these intra-configurational transitions are only weakly allowed, the lifetimes are generally quite long, of the order of μs – ms . Figure 40.2 shows some of the observed transitions in the case of the Pr^{3+} ion. There are further constraints on possible transitions which arise from an analysis of the angular momenta of the initial and final states. For example, a transition between two states both of which have $J = 0$ is forbidden since there is no angular momentum change as required for a photon; similarly for dipole transitions we require $\Delta J = 0, \pm 1$.

The transition probability per second for spontaneous emission [40.6] is given by

$$P_{ij} = \frac{64\pi^4\nu^3}{3hc^3} |r_{ij}|^2, \quad (40.3)$$

where ν is the frequency of the transition, h is Planck's constant, c is the velocity of light, and $|r_{ij}|$ is the matrix element of the electric dipole operator \mathbf{er}_{ij} between the two states i and j , and e is the electronic charge. For absorption, this must be multiplied by N , the mean number of photons with energy $h\nu$, which thus incorporates the effect of the incident beam intensity. Experimentally, one measures an absorption coefficient k as a function of energy $k(E)$ [40.6] which is linked to P_{ij} through,

$$\int k(E)dE = N_i \left(\frac{\pi e^2 h}{nmc} \right) \left(\frac{n^2 + 2}{3} \right)^2 f_{ij}, \quad (40.4)$$

where n is the refractive index of the crystal environment, m is the electronic mass, N_i is the concentration of the luminescent centres, and f is the *oscillator strength* for the transition. For both absorption and emission, the dimensionless oscillator strength f_{ij} defined as [40.6]

$$f_{ij} = \frac{8\pi^2 m \nu}{3h e^2} |r_{ij}|^2 \quad (40.5)$$

is often quoted to compare the relative transition probabilities. For an electron harmonic oscillator, $\sum f_{ij} = 1$, and so oscillator strengths of the order of 0.1–1 are strongly allowed transitions.

40.1.2 Transition-Metal Ions

Transition-metal ions from the 3d series are characterised by a much stronger interaction with the crystalline environment than the 4f ions since there is no equivalent of screening by the 5s, 5p outer shells. In addition, the spin-orbit coupling is weaker, and so the order

of perturbation is reversed: the atomic L , S multiplets are split by the crystal field, with spin–orbit coupling being a smaller interaction. Intra-configurational transitions are again strictly forbidden, but become weakly allowed by inter-configurational mixing through odd-parity crystal fields, and by odd-parity vibrations. The result of this is that the strongest selection rule after parity is that transitions should have $\Delta S = 0$, since the electric dipole operator does not involve spin. The other major difference, again due to the strength of the crystal-field interaction, is that transitions which are purely electronic, the so-called zero-phonon lines, are rarely observed. Rather what are seen are broad bands which correspond to the simultaneous excitation of an electronic transition and vibrational transitions, which overlap to give the broad observed bands. In particular, transitions involving odd-parity vibrations have a high transition probability through the effect of configuration admixing. This will be considered in a following section. The most commonly observed luminescent ions are those from the d^3 configuration (Cr^{3+} , Mn^{4+}) and from the d^5 configuration (Mn^{2+}).

40.1.3 s^2 Ions

The $5s^2$ (e.g. Sn^{2+} and Sb^{3+}) ions and $6s^2$ (e.g. Tl^+ , Pb^{2+} , Bi^{3+}) ions are of considerable importance because transitions to and from the excited s^1p^1 states are Laporte-allowed. The interaction of the p state with the

crystalline environment can be very strong, and so broad spectra are often observed.

40.1.4 Semiconductors

Luminescence in semiconductors is dominated by near-band-gap luminescence arising from recombination of electrons and holes. This process is most efficient in direct-band-gap materials such as ZnS and GaP rather than indirect-gap materials such as Si and Ge because the transition probability requires conservation of wavevector, but the photon wavevector is ≈ 0 on the scale of the Brillouin zone. Hence creation or destruction of a phonon is required for band-to-band luminescence in indirect-gap materials, which is less probable. The near-edge emission may correspond to luminescence from a variety of shallow energy-level structures such as free or trapped excitons, or from donor–acceptor recombination. These are both examples of electronic systems with spatially extensive wavefunctions, in contrast to the atomically localised $3d$ and $4f$ wavefunctions considered earlier. However, it is also possible to observe *deep-level* luminescence from transition-metal ions and rare earths in semiconductors provided that the electron affinities and band-gap energies are such that the pertinent energy levels fall in the band gap. Since semiconductors are discussed elsewhere in this volume, we shall not consider them further here.

40.2 Interaction with the Lattice

For rare-earth ions, the interaction with the vibrations of the crystal lattice can be ignored for most purposes; the observed luminescence spectrum consists of sets of sharp electronic transitions. But for other luminescent ions which interact strongly with the vibrating ions of the surrounding crystal, the incorporation of the latter is critical to explaining the observed spectra. The simplest model of ion–lattice interactions is to consider only the N nearest neighbour ions and their atomic displacements X_n , Y_n , Z_n , ($n = 1, N$) in Cartesian coordinates. The vibrational Hamiltonian involves cross terms in these coordinates, but may be transformed to harmonic form if symmetry-adapted forms of these coordinates (*normal modes*) are used instead of the actual displacements. For example, the so-called breathing mode Q_b , for an octahedrally coordinated ion takes the form

$$Q_b = (Z_1 - Z_2 + X_3 - X_4 + Y_5 - Y_6)/6. \quad (40.6)$$
